RESUMO

Esta tese apresenta um processo inovador para identificar requisitos potencialmente inovadores no projeto de trens de engrenagens planetárias (PGTs) utilizados em transmissões automáticas (ATs). Uma abordagem multidisciplinar, integrando ciência de mecanismos e máquinas, teoria dos grafos e técnicas avançadas de ciência de dados, é empregada para abordar esta desafiadora tarefa de projeto. Para viabilizar a análise, novos conceitos de juntas redundantes e virtuais são introduzidos, permitindo uma representação aprimorada de mecanismos de engrenagens planetárias (PGMs) em modelos de grafos. Também propõe uma equação geral de mobilidade revisada para PGMs, permitindo a análise integral dos mecanismos sem necessidade de simplificação. Além disso, novas métricas de complexidade estrutural e capacidade funcional são desenvolvidas, suportando avaliações comparativas abrangentes de PGMs. O processo apresentado envolve a construção de um banco de dados abrangente de PGMs, seguido por análise estratégica de atributos e descoberta de lacunas inovadoras. Este processo foi aplicado em um estudo de caso de 155 transmissões automotivas (6-10 velocidades), analisando 143 atributos distintos e resultando na identificação de treze conjuntos de atributos inovadores com múltiplos potenciais construtivos. Com base em um desses conjuntos, dois PGMs potencialmente inovadores foram sintetizados. Esta pesquisa também resultou em um valioso banco de dados enriquecido e uma extensa revisão da literatura sobre PGTs automotivos. Embora o tamanho do banco de dados seja atualmente limitado pela natureza meticulosa da extração de dados, uma aplicabilidade mais ampla é prevista através da futura automação do processo de coleta de dados e da integração de modelos de aprendizado de representação de grafos (GRL).

Palavras-chave: trens de engrenagens planetárias; transmissão automática; projeto de mecanismos; inovação; teoria dos grafos; ciência de dados.

RESUMO EXPANDIDO

Introdução

As transmissões automotivas desempenham um papel essencial na otimização do desempenho de veículos, abordando desafios de transferência de potência, conversão de torque, eficiência de combustível e adaptabilidade. Enquanto o mercado ainda é dominado por veículos com motor de combustão interna (ICE), emergem oportunidades para avanços em desempenho e redução de emissões, paralelamente ao crescimento dos veículos elétricos (EVs). Diversos tipos de transmissão, incluindo manual (MT), mecânica automatizada (AMT), automática (AT), de dupla embreagem (DCT) e continuamente variável (CVT), oferecem características operacionais e de eficiência distintas. Historicamente, as transmissões automáticas evoluíram consideravelmente desde o século XIX, focando em eficiência de combustível e redução de emissões. Os AT modernos incorporam complexos trens de engrenagens planetárias (PGTs), variando de 4 a 10 velocidades. O projeto de novos PGTs para AT requer essencialmente um estudo aprofundado da estrutura cinemática do mecanismo, o que se apresenta como uma tarefa desafiadora. Embora seja um tema amplamente estudado, exige uma combinação única de criatividade e habilidades técnicas. Os métodos tradicionais de projeto frequentemente se baseiam em adaptação ou busca exaustiva, havendo limitações de escopo em ambos os casos. Portanto, o principal desafio é identificar com maior precisão e detalhamento os requisitos de projeto de maior potencial inovador, minimizando o investimento dedicado a soluções inviáveis. Nesse contexto, a análise de mecanismos obtidos em fontes como patentes, pesquisa acadêmica e dados industriais, aliada com técnicas avançadas de ciência de dados, emerge como uma estratégia valiosa para impulsionar a inovação.

Objetivos

Esta pesquisa tem o intuito de criar e explorar bases de dados extensas e diversificadas para revelar oportunidades inovadoras nos projetos de mecanismos de engrenagens planetárias (PGMs) automotivos. O principal objetivo é desenvolver um processo para auxiliar projetistas na identificação de tais oportunidades. Durante o estudo de diferentes mecanismos de transmissão automotiva, identificou-se que as representações por grafo existentes e a equação geral de mobilidade se limitam à análise da cadeia cinemática, inviabilizando uma abordagem abrangente. Portanto, um objetivo adicional desta tese é apresentar um arcabouço para análise comparativa de mecanismos PGT completos englobando: conceitos de juntas redundantes e virtuais na representação por grafos, equação geral de mobilidade atualizada, e métricas para avaliação da complexidade estrutural e capacidade funcional. Essas métricas permitem avaliações comparativas minuciosas dos projetos de PGM. Os objetivos específicos incluem a investigação de processos de análise e síntese de PGMs, a construção de um banco de dados abrangente, o estabelecimento de abordagens sistemáticas para identificar atributos relevantes, descobrir lacunas inovadoras para os requisitos de projeto e implementar o processo em um estudo de caso com transmissões automáticas.

Metodologia

Foi proposto um processo que integra conceitos multidisciplinares — incluindo análise de requisitos de projeto, ciência de mecanismos e máquinas, bancos de dados de

patentes e teoria dos grafos — com métodos avançados de *data science*, como a descoberta de conhecimento em bases de dados (KDD) e técnicas de mineração de dados. Está estruturado em quatro fases, cada uma com quatro etapas distintas, visando ampliar o domínio de análise dos mecanismos para identificar atributos não-triviais que usualmente não são considerados nos projetos. A primeira fase é a *Pesquisa de Mecanismos*, onde um estudo abrangente reúne dados e informações relevantes de mecanismos em bases de patentes, acadêmicas e industriais. A segunda fase é o *Enriquecimento de Dados*, em que é criado um dicionário diversificado de atributos para caracterização dos mecanismos e formação da base de dados completa. A terceira fase é a *Análise de Atributos*, quando os mecanismos e atributos da base de dados são revisados quanto à sua integridade, avaliados estatística e estrategicamente, e os atributos mais relevantes para o projeto dos mecanismos são selecionados. A quarta fase é a *Descoberta de Lacunas*, compreendendo a varredura nos atributos mais relevantes para a descoberta de lacunas nos dados, que na sequência são priorizadas, combinadas em *clusters* e, as mais promissoras, são selecionadas como potenciais conjuntos de inovações que servem como requisitos para o projeto de novos mecanismos. Apesar deste estudo ser focado em transmissões automotivas, o processo foi proposto para atender a projetos de mecanismos em geral.

Resultados e Discussão

O processo proposto foi aplicado como estudo de caso a transmissões automotivas automáticas de 6 a 10 marchas baseadas em mecanismos de engrenagens planetárias (PGMs), sendo construído um banco de dados com 160 mecanismos caracterizados por 186 atributos. Após revisão e limpeza dos dados, resultaram 155 mecanismos e 143 atributos distintos, que foram analisados em contextos de grupo único e, também, agrupados por condição comercial, número de conjuntos planetários (PGSs) e número de marchas à frente. A análise estratégica dos principais corpos fixo (F), entrada (IN) e saída (OUT) permitiu caracterizá-los quanto a sua constituição e acoplamentos. A análise estratégica sobre complexidade revelou que a métrica de complexidade estrutural proposta é mais precisa que outras métricas, diferenciando 143 mecanismos únicos, sendo altamente correlacionada com seu termo relativo à complexidade das juntas. Ainda, a métrica de complexidade estrutural foi utilizada em conjunto com a métrica de capacidade para apresentar um mapa de fronteira tecnológica dos mecanismos da base de dados. A seleção de atributos utilizou técnicas como *Random Forest*, *Recursive Feature Elimination (RFE)*, regularização L1 usando método Lasso e métodos estatísticos univariados para determinar os atributos mais relevantes conforme os contextos de análise previamente estabelecidos. Por fim, utilizando uma função própria para a descoberta de lacunas, foram selecionados 13 conjuntos de inovação envolvendo atributos topológicos e funcionais com múltiplos conjuntos de PGSs que podem ser aplicados como requisitos de projeto para novos mecanismos de transmissão planetária automotiva. Uma síntese baseada nas lacunas de inovação foi apresentada propiciando a descoberta de dois novos mecanismos em potencial. A pesquisa apresentou avanços significativos na análise e síntese de mecanismos de engrenagens planetárias (PGTs) automotivos, destacando-se:

1. Novos conceitos de juntas redundantes e virtuais permitem uma representação mais abrangente da estrutura dos mecanismos em modelos de grafos, considerando o PGM integralmente, facilitando a análise e o projeto de mecanismos complexos.

2. Nova equação geral da mobilidade revisada para PGMs possibilita o cálculo preciso da mobilidade de mecanismos de transmissões planetárias completos, considerando as juntas redundantes e virtuais.
3. Novos conceitos de complexidade estrutural e capacidade funcional fornecem uma avaliação mais completa, precisa e abrangente do mecanismos de PGT, auxiliando na tomada de decisões durante o projeto.
4. Novo processo de análise e descoberta de lacunas inovadoras em base de dados de mecanismos permite a identificação de lacunas inovadoras em bases de dados de mecanismos, abrindo caminho para o desenvolvimento de novos conceitos e soluções tecnológicas.
5. Aplicação do processo proposto em um estudo de caso comprovou sua viabilidade e efetividade na identificação de sete conjuntos de inovação relevantes para o projeto de novos mecanismos de PGT.
6. Processo de síntese baseado em conjuntos inovadores resultou no desenvolvimento de duas novas transmissões automotivas com potencial inovador.
7. Base de dados enriquecida com 143 atributos distintos representa um recurso valioso para pesquisas futuras na área de projeto de transmissões automotivas.

Considerações Finais

As contribuições científicas envolvem a revisão do grafo e da equação de mobilidade para PGMs, a introdução de métricas de complexidade e capacidade funcional, o desenvolvimento e a aplicação de um procedimento para identificar conjuntos de inovação, e a síntese de dois PGMs potencialmente novos, enriquecendo o processo de desenvolvimento de novos mecanismos. O estudo possui limitações, como o número restrito de instâncias na base de dados devido ao processo manual meticuloso que toma tempo na conversão de patentes em modelos na base de dados, influenciando a generalização dos resultados. A necessidade de competência técnica para a análise dos atributos também pode ser uma barreira para a adoção do processo. Trabalhos futuros deverão focar na automação da coleta de dados, expansão da caracterização dos PGMs, aprimoramento das métricas de complexidade e generalização do processo para outros mecanismos complexos. Utilizar modelos de aprendizagem por representação com grafos (GRL) para descoberta de conhecimento e mineração de dados é um caminho promissor. Em resumo, a pesquisa apresenta uma abordagem estruturada para identificar e analisar configurações inovadoras em PGMs, contribuindo significativamente para o avanço da pesquisa e projeto neste campo. Esforços futuros podem aprimorar ainda mais o processo, transformando-o em metodologia para ampliar sua aplicabilidade prática.

ABSTRACT

This thesis presents a novel process for identifying potential innovative requirements in the design of automotive planetary gear trains (PGTs) used within automatic transmissions (AT). A multidisciplinary approach, integrating mechanism and machine science, graph theory, and advanced data science techniques, is employed to address this challenging design task. To enable the analysis, this research introduces new concepts of redundant and virtual joints, allowing an improved representation of planetary gear mechanisms (PGMs) within graph models. It is proposed a revised general mobility equation for PGMs, allowing the full analysis of the mechanisms without the need for simplifications. Furthermore, new metrics of structural complexity and functional capability are developed, supporting comprehensive comparative evaluations of PGM designs. The proposed process involves constructing a comprehensive database of PGMs, followed by strategic feature analysis and discovery of potentially innovative gaps. This process was applied in a case study of 155 automotive transmissions (6-10 speeds), analyzing 143 distinct attributes and resulted in the identification of thirteen innovative feature sets with multiple candidates PGSs. Based on one of these sets, two potentially innovative PGMs were synthesized. This research also resulted in a valuable enriched database and an extensive literature review on automotive PGTs. While the database size is currently constrained by the meticulous nature of data extraction, broader applicability is envisioned through future automation of the data collection process and the integration of graph representation learning (GRL) models.

Keywords: planetary gear train; automatic transmission; mechanism design; innovation sets; graph theory, data science.

1 INTRODUCTION

Automotive transmissions are essential in optimizing vehicle performance by addressing requirements imposed by the limitations of both internal combustion engines (ICEs) and electric motors (EMs). These needs include power transfer from the engine to the wheels, torque conversion during startup, power distribution at different speeds, fuel efficiency optimization, and adaptability to different power sources.

Despite the growing presence of electric-powered vehicles (EVs) in the automotive market, ICE vehicles will remain dominant in the foreseeable future (ZHANG; MI, 2018). This is primarily due to existing challenges in the development of key electric vehicle technologies, such as battery energy density, durability, and charging time, as well as the lack of necessary infrastructure for widespread electric vehicle adoption.

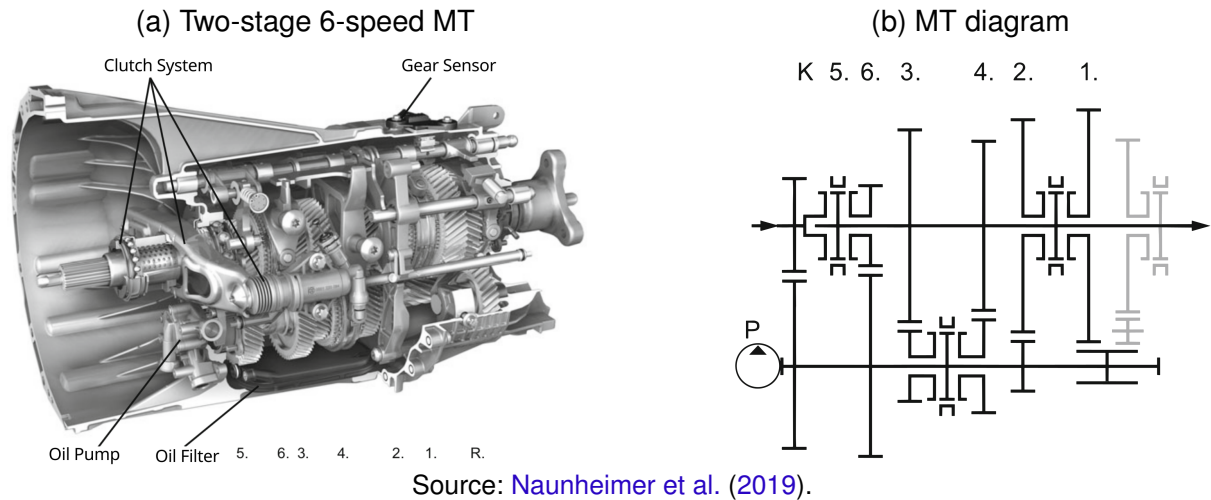

In 2022, according to ANFAVEA (2023), the estimated fleet of automobiles (passenger vehicles) in Brazil was approximately 38 million, being only 129,000 electric vehicles, representing 0.3% of the total. Despite the high expectations of transitioning towards electrification, 35% of global market share in 2030 according to IEA (2023), the combustion engine vehicle market remains significantly larger, providing opportunities to address challenges related to the limitations of ICE in terms of performance and emissions.

Currently, there are five mainstream transmission types for ICE passenger vehicles: manual transmission (MT), automated mechanical transmission (AMT), automatic transmission (AT), dual clutch transmission (DCT), and continuously variable transmission (CVT). A brief summary of each type is described below based on Naunheimer et al. (2011), Fischer et al. (2015), Zhang and Mi (2018) and Chen (2021).

Manual transmission (MT) is a mechanical transmission that enables manual gear shifting, providing variable speed ratios. It offers high transmission efficiency, torque transfer, and a simple structure. MT is commonly utilized in smaller vehicles and some sport cars, typically available in 5 or 6-speed variants. Recent MT advancements include compact designs with improved synchronizers and advanced lubricants. Although MTs are popular in Europe and emerging markets, ATs are gaining traction due to their improved fuel economy and reduced costs. As environmental standards rise, automated powertrains may become mandatory in some markets due to their efficiency and reduced emissions (FOLKSON; SAPSFORD, 2022). Figure 1 provides an example of a 6-speed manual transmission utilized by Mercedes-Benz in their C-Class passenger vehicles during the 2000s.

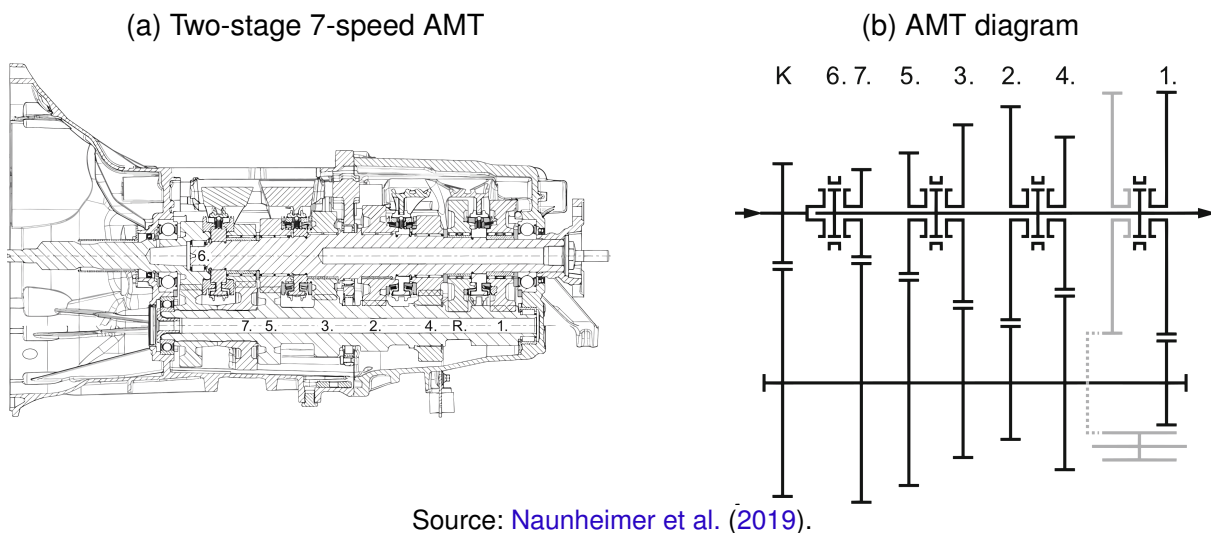

Automated mechanical transmission (AMT) utilizes electronic control, hydraulic, or electric actuation systems to automate clutch engagement, gear selection, and shifting. AMT offers high transmission efficiency, ease of manufacturing, and cost-effectiveness. It is predominantly employed in mini and small cars but has limited

Figure 1 – 6-speed manual transmission (MT) for passenger cars Mercedes-Benz SG6-300.

potential for larger models due to power failure during shifts. AMT includes electrically controlled hydraulic AMT (with an electrohydraulic actuator) and electrically driven AMT, with the latter featuring a simpler structure, improved reliability, and lower cost, representing the mainstream trend in AMT development. Figure 2 shows an example of a 7-speed automated manual transmission utilized by BMW in M5 and M6 models of passenger vehicles since 2005.

Figure 2 – 7-speed automated manual transmission (AMT) for passenger cars Getrag 247.

Automatic transmission (AT) allows for the automatic shifting of gears without requiring driver input. The hydraulic automatic transmission is the most common type and operates using a combination of a planetary gear train (PGT), hydraulic controls, and a torque converter. Until the turn of the century, 4-speed ATs were popular in small cars despite reduced comfort and economy. Currently, six-speed ATs are stan-

standard equipment across the industry, and luxury brands use 7-speed and 8-speed ATs for improved performance and efficiency (ZHANG; MI, 2018). Advanced options like 9-speed and 10-speed AT have been successfully developed by automotive companies like Daimler (DÖRR et al., 2014), ZF (GAERTNER; EBENHOCH, 2013), Aisin (SUZUKI et al., 2017), and GM (MARTIN; HENDRICKSON, 2018), among others. Figure 3 shows an example of a 9-speed automatic transmission utilized by Mercedes-Benz in several passenger car models such as the C, E, S, GL, and AMG Classes. Additionally, Nissan and Infiniti's top level vehicles have also been granted permission to use this transmission (HENRY, 2015).

Figure 3 – 9-speed automatic transmission (AT) for passenger cars Mercedes-Benz 9G-Tronic.

Source: (a) Dörr et al. (2014), and (b) Naunheimer et al. (2019).

Dual clutch transmission (DCT) arranges transmission gears on two input shafts connected with two clutches, combining the advantages of AT and AMT. It delivers high transmission efficiency, simplicity, and cost-effectiveness. DCT is classified into dry DCT (DDCT) and wet DCT (WDCT). Electric DDCT, featuring a simple and reliable structure, is expected to become the mainstream choice for small to medium torque transmissions, while WDCT, with a high carrying capacity, is suitable for application in intermediate and higher-class vehicles (CHEN, 2021). Figure 4 shows an example of a 7-speed dual clutch transmission introduced in 2008 by Volkswagen and utilized in all models from the Polo to the Arteon (VOLKSWAGEN, 2023). Manufacturers such as BMW believe that the 8-speed planetary AT can perform as well as a DCT in performance vehicles with the right software and calibration (MARSHALL, 2022).

Continuously variable transmission (CVT) optimizes engine and powertrain performance for smooth operation, enhanced safety, and improved emissions. Launch devices include torque converters and clutches, with a planetary gear set providing a reverse gear. Park lock is common. Two common types of CVTs are metal pushing V-belt and chain CVT. Metal pushing V-belt CVT offers unparalleled comfort but requires cost and maintenance improvements, while chain CVT has higher transmission efficiency and a compact structure but may produce some noise. Figure 5 provides an example

Figure 4 – 7-speed dual clutch transmission (DCT) for passenger cars Volkswagen DQ200-7F.

Source: Fischer et al. (2015).

of Audi Multitronic CVT utilized in passenger cars such as A4, A5, A6 and A7 models up to 2014 (DEGASPERI, 2014).

Figure 5 – Continuously variable transmission (CVT) for passenger cars Audi Multitronic.

Source: Fischer et al. (2015).

A comparative analysis of the five main transmission types can be seen in Tab. 1.

Additionally, there is a projected substantial increase in the utilization of hybrid

transmissions (HT), driven by the expanding market share of hybrid electric vehicles (HEV) and battery electric vehicles (BEV). This shift towards hybrid transmissions aligns with evolving consumer demands and industry trends in the automotive sector. [Figure 6](#) shows an example of a two-mode dedicated hybrid transmission (DHT) developed in cooperation by BMW, Chrysler, Daimler, and General Motors in 2009. The ML 450 HYBRID from Mercedes used this technology, which integrated two EMs into the housing as permanently excited synchronous machines ([NAUNHEIMER et al., 2019](#)).

Figure 6 – Hybrid transmission for passenger cars BMW/Chrysler/Daimler/GM.

(a) Two-mode DHT

(b) DHT diagram

Source: [Naunheimer et al. \(2019\)](#).

This research focuses on the topology of PGT's automatic transmissions, a complex yet critical component of modern automotive transmissions. The [ATs](#) have gained significant importance in the automotive industry since the 19th century, as highlighted in [Naunheimer et al. \(2019\)](#). In 1834, Bodmer designed a partially power-shiftable

planetary gear (Fig. 7), followed by H. Rieseler in 1925, who designed an automatic transmission with a torque converter and rear-mounted planetary transmission. The essential components of Rieseler's transmission, such as the torque converter, planetary gear, and shifting mechanisms, became the foundation for conventional automatic transmission systems as found these days. The General Motors Hydramatic, introduced in 1939, marked the first mass-produced automatic transmission, rapidly gaining popularity in the USA after World War II. In Europe, automatic transmissions had a lower market share until German manufacturers like Borgward, Daimler-Benz, and ZF developed their own designs in the 1950s and 1960s. Over time, automatic transmissions underwent continuous development for fuel efficiency, with electronic-hydraulic control units becoming the standard in the mid-1990s.

Figure 7 – Shiftable planetary gear transmission in 1834.

Source: [Naunheimer et al. \(2019\)](#).

Advancements include slip-controlled torque converter lock-up clutches, transmissions with up to 10 speeds for improved gear ratio adaptation, and the reintroduction of claw shift elements in 2013 to reduce drag losses. At the moment, according to [Chen \(2021\)](#), ATs are found in 4 up to 10 speeds. Smaller or older cars usually carry 4-speed ATs, which has poor comfort and economy. 5-speed ATs are slightly better but has an abrupt shift and limited late development space. 6-speed ATs are the mainstream for modern small, compact, and middle-sized vehicles. High-end models have 7 or 8-speed ATs, while larger vehicles have 9 or 10-speeds ATs. Increasing the number of ratios allows for optimum engine conditions, but frequent shifting has disadvantages, including higher energy consumption in the hydraulic shift system and a poor driver experience referred to as 'shift busyness' ([FOLKSON; SAPSFORD, 2022](#)).

The PGT technological advancements in automotive transmissions boasted several advantages, including a wide range of motion states, a compact design, high power density, improved efficiency, and seamless shifting. PGTs typically consist of a hydrodynamic torque converter in combination with planetary gear sets (PGS), enabling the power transmission through gear clutches and gear rolling to achieve a high number

of gear ratios. The electronic control system is essential in operating the brakes and clutches through electrohydraulic valves, ensuring smooth and efficient shifting.

Xu et al. (2018) offers an insightful review of the progress in automotive transmission technology. This includes the development of new transmission schemes assisted by computer-aided programs, optimization of transmission parameters, and a shift towards electrification in the industry. The challenges highlighted encompass optimizing speed numbers, determining the appropriate number of degrees-of-freedom (DOF), and enhancing mechanical and hydraulic systems, among others.

In the innovation field concerning automotive ATs, the topological structure of PGTs stands out as the central area of interest. The design complexities of these mechanisms dictate key transmission specifications, including the number of gears and their sequential arrangement during shifting. Yet, the design process for new PGTs is intricate, requiring a blend of creativity and technical skills to address specific engineering challenges within set constraints.

Historically, reliance on designers' intuition and experience in early design phases can occasionally result in suboptimal outcomes, potentially limiting innovation (TSAI, 2001). The conceptual phase, where mechanisms are designed, is particularly challenging due to its requirement for creativity and knowledge (YAN, 1992). According to Ding et al. (2013), traditional methods for mechanism design are time-consuming and have limitations in conceiving all possible kinematic structures. As a result, deriving the optimal solution for the design task becomes challenging, if not impossible.

In the literature, two main approaches for mechanism design have been identified (FREUDENSTEIN; MAKI, 1979). The atlases-based methodologies involve designing from a library of elementary mechanisms grouped according to their function. While these methodologies are relatively easier to analyze and design, they have limitations in terms of the number of possible solutions due to structural constraints and restrictions (KOTA; CHIOU, 1992; SUBRAMANIAN; WANG, 1995; OU et al., 2010; TSAI et al., 2010; HE; HUANG, 2016; HU et al., 2017). On the other hand, the abstraction-based methodologies involve designing based on structural characteristics derived from abstract representations of mechanisms, such as equations, matrices, and graphs (HARTENBERG; DENAVIT, 1964; FREUDENSTEIN; MAKI, 1979; CHATTERJEE; TSAI, 1994; YAN, 1998; MURAI, 2019; DING, 2015). This approach offer more numerous and detailed solutions with greater potential for innovation compared to atlases-based approaches, but they can be more time-consuming and challenging to visualize in early stages (YAN, 1998).

An undeniable challenge in mechanism design is the precise identification of key requirements and parameters driving the creation of new mechanisms, while minimizing the time spent on non-viable solutions. This becomes particularly crucial in abstraction-based methodologies, where the high level of abstraction makes it challenging for

designers to identify parameters significantly affecting design and performance of the mechanisms.

Researchers and designers frequently turn to diverse information sources to improve mechanism design processes, with patents being a particularly valuable repository of technological insights (WIPO, 2015; ARISTODEMOU; TIETZE, 2018). Comprehensive patent analyses can reveal existing solutions and highlight potential design innovations (HOELTGEBAUM et al., 2016a; MARTINS et al., 2018; OLIVEIRA E COSTA et al., 2018). Ding and Cai (2019) further emphasized the essence of patent analyses by conducting an in-depth examination of PGTs in 673 ATs. Their research accentuated the necessity to comprehend the structural attributes of PGTs to augment AT performance and instigate innovation. Notably, the study addressed the pseudo-isomorphism challenge, paving the way for the development of novel PGT configurations, and unearthed important challenges for future works, encompassing the efficient synthesis of PGT configurations and the optimization of AT design processes. However, the study's primary focus remained on basic mechanism characteristics, such as the number of links, degrees of freedom, and link assortments.

Several methods involve patent in engineering design, including TRIZ, design-by-analogy, concept-knowledge (C-K) theory, and genetic algorithms (ALTSULLER et al., 1999; JEONG; KIM, 2014; FELK et al., 2011; KOZA et al., 2004). Hoeltgebaum et al. (2016b) introduced a patent survey methodology specifically tailored for automotive mechanisms, such as gear trains and suspensions. This methodology delineates a structured six-step process, encompassing preliminary searches, meticulous analysis, and the classification of key mechanisms. This approach is significantly dependent on the designer's subjective analysis and might overlook essential design characteristics. The resulting narrowing of technological mapping may unintentionally exclude critical information necessary for innovative solutions.

Despite the extensive research on the subject of automotive planetary gear trains, it is evident that there are still significant gaps and challenges that can be improved.

While the potential of patent research in revealing valuable insights is recognized, current methodologies appear to possess limitations. Specifically, the designer's limited capacity to deal with a large and diverse number of mechanism characteristics reduces the possibility of delving deeper into the inherent potential of these surveys (CHEN, 2021). Such restrictions prevent accessing less trivial patterns of mechanism characteristics that may have the potential for innovation. Moreover, the current landscape lacks a holistic and comprehensive process to support the designer, emphasizing the opportunity to improve methodologies.

Discovering innovative requirements for designing new automotive planetary transmissions includes the need for a systematic approach to innovation, determining relevant parameters and characteristics for evaluation, and identifying gaps with

potential for innovation in the topology of the mechanisms.

1.1 THESIS OBJECTIVES

This thesis aims to **develop a systematic process for identifying potential innovative gaps within the design requirements of automotive planetary gear train mechanisms in a comprehensive and diverse database**. The central research question guiding this work is: *How can an extensive and diverse database support the discovery of potential innovative gaps in automotive planetary gear train designs?*

During the study of different automotive transmission mechanisms, it was determined that existing graph-based representations and the general mobility equation are limited solely on kinematic chain analysis, making the comprehensive study unfeasible. Therefore, an additional objective of this thesis is to **present a framework for the comparative analysis of complete PGT mechanisms**. This framework encompasses the *concepts of redundant and virtual joints* within the graph representation, a *revised form of the general mobility equation*, and *metrics for assessing structural complexity and functional capabilities*.

To accomplish the primary objective, the research is decomposed into specific objectives, each serving as a systematic step towards the overall goal:

1. To investigate analysis and synthesis processes in automotive planetary gear trains to identify diverse evaluation features.
2. To construct a structured database centered on automotive **ATs** based on planetary gear trains, analyzing inherent mechanism features.
3. To establish a systematic approach to identify relevant features in synthesizing automotive planetary gear trains.
4. To develop an analysis method for discovering innovative gaps in the design requirements of automotive planetary gear trains.
5. To implement the process in a case study to analyze results and extract insights for innovation in automotive AT design.

1.2 METHODOLOGY APPROACH

The process proposed in this research integrates multidisciplinary concepts — including analysis of design requirements, mechanism and machine science, patent analysis and graph theory — with advanced *data science* methods, such as data mining and feature selection. The process is systematically structured into four sequential phases, each comprising four distinct steps. Its framework was intentionally designed to broaden the scope of mechanism analysis, capturing non-trivial features often not considered in conventional designs. The first phase is *Mechanism Survey*, where a

comprehensive study brings together relevant data and information from mechanisms in patent, academic and industrial sources. The second phase is *Data Enrichment*, in which a diverse dictionary of features is created to characterize the mechanisms and complete the database construction. The third phase is *Feature Analysis*, when the mechanisms and features of the database are revised for their integrity, evaluated statistically and strategically, and the most relevant features for the design of the mechanisms are selected. The fourth phase is *Gap Discovery*, comprising scanning the most relevant features for discovering gaps in data, which are then prioritized, combined into *clusters* and, the most promising, are selected as potential innovation sets that can be used as requirements for the design of new mechanisms.

Although this study is focused on automotive transmissions, the process was proposed to cover mechanism designs in general.

1.3 CONTRIBUTION AND EXPECTED OUTCOMES

This thesis contributes to the fields of analysis and synthesis of automatic automotive transmissions, specifically focusing on defining potential innovative design requirements for the topology of planetary gear train mechanisms. It is introduced new equations for the characterization of PGTs and a systematic process for database investigation and requirement discovery that has the potential for innovation in the synthesis of new automotive transmissions, with potential extensions to other types of mechanisms.

By conducting extensive and diverse analysis of features involved in the analysis and synthesis process, it is expected to identify characteristics that are often overlooked in traditional design processes. To the best of the author's knowledge, the process introduced in this thesis is the first to incorporate data mining techniques for discovery of potential innovative design requirements in automatic automotive transmissions based on planetary gear trains.

The main contributions of this thesis are summarized below, organized by their level of relevance:

1. **Novel Concepts of Redundant and Virtual Joints:** The introduction of innovative concepts for redundant and virtual joints has enabled the enhanced representation of PGT mechanisms in graph form. This advancement facilitates improved modeling and analysis of the complete structure of these mechanisms.
2. **Revised General Mobility Equation:** A refined general mobility equation for calculating the mobility of PGT mechanisms has been proposed. This equation expands the analytical capabilities to encompass complete mechanisms without the need for simplifications.

3. **Novel Structural Complexity and Functional Capability Metrics:** The development of novel concepts for structural complexity and functional capability has paved the way for more comprehensive comparative evaluations of PGT performance. These concepts provide valuable support to designers during the synthesis process.
4. **New Process for Analyzing and Discovering Innovative Gaps in Mechanism Databases:** A systematic process for identifying innovative gaps in mechanism databases has been created. This process opens up avenues for the development of new concepts and technological solutions.
5. **Application of the Proposed Process in a Case Study:** The proposed process for analyzing and discovering innovative gaps was applied in a case study involving 155 automotive transmissions with 6 to 10 speeds. This application resulted in the identification of thirteen innovative sets of attributes with potential for developing new mechanisms.
6. **Synthesis Process Based on Innovative Sets:** Building upon one of the discovered innovative sets of attributes, two potentially innovative automotive transmissions were developed through the synthesis of new planetary gear train mechanisms.
7. **Enriched Database with 186 Attributes:** This thesis has led to the development of a database comprising 155 automotive planetary transmissions enriched with 180 analyzed attributes for each transmission. This comprehensive dataset provides a valuable resource for future research.
8. **Extensive Literature Review:** The thesis presents an extensive review of the literature on automatic automotive transmissions based on planetary gear trains. This review provides a solid foundation for the new concepts, methods, and results presented in the research.

1.4 THESIS OUTLINE

In alignment with the stated objectives, the thesis structure has been organized into chapters as detailed below.

In [Chapter 1](#), an overview of the automotive transmissions landscape is given. The debate surrounding the design of new mechanisms is initiated, with problems and challenges being identified. The main research question of the thesis is introduced, followed by the objectives that have been established to explore, assess, and suggest potential solutions. The anticipated contributions of this work are then delineated.

In [Chapter 2](#), a detailed examination of automatic transmissions that employ planetary gear trains is presented. This encompasses their definitions, types, appli-

cations, structural characteristics, methods of analysis, synthesis, and the challenges linked with PGTs.

In [Chapter 3](#), an in-depth revision of the mobility equation, particularly as it pertains to planetary gear trains with redundant and virtual constraints, is undertaken. Metrics for evaluating the structural complexity and performance capability of the PGTs are also introduced.

In [Chapter 4](#), a novel process for the analysis and synthesis of mechanisms, including planetary gear trains, is introduced. This process is divided into four distinct phases: a survey of mechanisms, data enrichment, feature analysis, and gap discovery. Each phase is presented in detail, aiding in the identification of requirements for potential innovations in mechanism design.

In [Chapter 5](#), a preliminary implementation of the proposed process is applied to the analysis of planetary automatic transmissions ranging from 6 to 10 speeds. Subsequently, the obtained innovations sets and pertinent discussions are presented.

In [Chapter 6](#), a synthesis process based on gaps and innovation sets is presented to design potentially new PGMs.

In [Chapter 7](#), a summary of the achieved objectives and the scientific contributions made is provided. References to pertinent publications, the challenges and restrictions of the thesis, and suggestions for future research directions are also offered.

2 REVIEW OF AUTOMOTIVE PLANETARY GEAR TRAINS

Automatic transmissions consist of mechanisms with complex topologies and necessitate an extensive study to fully mastery their design. This chapter offers a comprehensive analysis of planetary gear train mechanisms, specifically concentrating on the analysis and synthesis of their kinematic structures within the scope of automotive transmission design.

Initially, a comprehensive overview of automatic transmissions is provided, delineating their primary functional requisites. Subsequently, definitions pertinent to mechanism and machine science are reviewed, followed by a detailed analysis of the planetary gear train structure. In conclusion, the principal methodologies applied to these mechanisms are presented, emphasizing the significance of design specifications and requirements specially tailored for planetary gear trains.

2.1 AT OVERVIEW

Automatic transmissions based on planetary gear trains are widely employed in passenger cars. These transmissions consist of a torque converter, an oil pump, a planetary gear train, a set of shift couplings (clutches and brakes), and a shifting controller. This kind of transmission is also known as conventional automatic transmissions (AT). [Figure 8](#) illustrates a typical configuration of automotive AT based on PGTs.

Figure 8 – Configuration of a 3-speed AT based on Simpson PGT.

Source: Adapted from [Halderman and Birch \(2017\)](#).

The torque converter works as a fluid coupling between the engine and transmission, enabling torque multiplication during acceleration, smooth vehicle stops without engine stalling, and seamless gear changes while transmitting torque from the engine to the wheels.

Oil pumps are responsible by ensuring a consistent flow and pressure of fluid in the hydraulic circuit of the AT. This is essential for lubricating and cooling moving parts,

supplying fluid to the valve body, and maintaining fluid circulation within the torque converter. The oil pump is directly connected to the engine speed through the torque converter and relies on the operation of the ICE to properly pressurize the fluid.

Shift couplings (SC), also referred to as shifting elements, are used in the design of AT to provide frictional power transfer among internal transmission elements. This enables torque supply between different ratios without interrupting the power flow to the output shaft. Shift quality, particularly shift impact and shift time, holds significant importance in transmission development and calibration (FISCHER et al., 2015). When one element is stationary (housing), it is referred to as a brake (B) or reaction coupling. On the other hand, when both elements are movable, it is referred to as a clutch (C) or coupling clutch. Additionally, one-way clutches (OWCs) allow rotation in one direction while blocking it in the opposite direction, contributing to smoother gear changes during shifting (ZHANG; MI, 2018).

Most modern automatic transmissions incorporate a Transmission Control Module (TCM) to manage their operation. The TCM communicates with the vehicle's Electronic Control Unit (ECU) to ensure proper shift timing and quality. The actuation of each shift coupling is achieved through hydraulically controlled electrovalves (solenoids) contained within a valve body submerged in transmission fluid. The TCM utilizes various sensors such as rotation, pressure, temperature, and position to adapt transmission operation to optimal conditions, a process known as transmission adaptive learning or adaptive control.

While there are various technologies associated with the systems mentioned above in automatic transmissions, their detailed discussion is beyond the scope of this thesis, which focuses on PGTs. For more in-depth understanding of these topics, it is recommended to refer to specific literature (CHEN, 2021; NAUNHEIMER et al., 2019; HALDERMAN; BIRCH, 2017; BOSCH, 2014).

2.1.1 AT Functional Requirements

According to Naunheimer et al. (2011), the main functions of a vehicle transmission are to:

- Enable the vehicle to move-off from rest.
- Adapt power flow by:
 - converting output torque and speed,
 - enabling reverse motion.
- Enable permanent power transmission with minimal loss.
- Control power matching.

The inherent characteristics of PGTs make them an essential component in achieving multiple gear ratios and enabling smooth shifting operations in automatic

transmissions.

To ensure optimal performance and fuel economy, these transmissions must meet specific functional requirements that are summarized as follows (TSAI, 2001):

1. Provide multiple speed ratios, including reverse, by engaging different links within the transmission mechanism.
2. Have a wide overall speed ratio range to accommodate both high-load and low-load operations.
3. Ensure small step ratios between speeds, following an adequate progression for smooth and gradual transitions.
4. Enable single clutch-to-clutch shifts for seamless and uninterrupted gear changes.

In addition to the main functional requirements, there are ancillary requirements that impact the competitiveness of the transmission system (NAUNHEIMER et al., 2011). These include operational reliability, gearbox costs, ease of repair, ease of operation, power matching, efficiency, installation dimensions and weight, customization, and emissions (noise, oil, etc.).

The arrangement of the driving wheels and the engine in the vehicle also exerts an important influence on the transmission design. There are three main configurations according to driving wheels: front-wheel drive (FWD), rear-wheel drive (RWD), and all-wheel drive (AWD). Additionally, the drivetrain can be arranged in two ways based on the relative direction of its main rotating shaft to the wheel axle: transverse (parallel) and longitudinal (perpendicular).

A specific type of transmission commonly used in FWD vehicles and some RWD configurations is the transaxle. It combines the functions of the transmission and a differential into a single integrated unit, simplifying the drivetrain layout and reducing weight. The Fig. 9 illustrates transaxle transmissions in transverse (Fig. 9a) and longitudinal (Fig. 9b) mountings for a front-wheel drivetrain.

The importance of these supplementary requirements can be assessed through a requirements profile, which aids in identifying design and economic goal conflicts and seeking suitable compromises based on assigned weightings.

2.1.1.1 Gear ratios

The gear ratio i_G is the relationship between the input shaft (IN) and the output shaft (OUT) of a transmission as follows:

$$i_G = \frac{n_{IN}}{n_{OUT}} = \frac{T_{OUT}}{T_{IN}} = \frac{Z_{OUT}}{Z_{IN}} \quad , \quad (1)$$

where n denotes speed, T represents torque, and Z indicates the number of teeth on the respective shafts.

Figure 9 – Drivetrain arrangements for a front-wheel driven vehicle.

Source: Adapted from Halderman and Birch (2017).

In planetary gear trains, gear ratios are achieved by engaging and disengaging shift couplings to create power flow between the input and output shafts. According to the engaged couplings, these power flow provide the following conditions (Tab. 2):

Table 2 – Gear ratio conditions.

Gear ratio	Condition
$i_G < 0$	Reverse
$i_G = 0$	Neutral
$i_G > 1$	Underdrive (speed reduction)
$i_G = 1$	Direct-drive (1:1)
$0 < i_G < 1$	Overdrive (speed multiplication)

Source: Author.

Specific reduction and multiplication transmission ratios are achieved by varying the number of teeth on the gears. To avoid continuous noise repetition, engineers usually avoid using whole number transmission ratios (e.g., 3:1 or 4:1) in gear pairs and instead apply a margin of approximately 10% (e.g., 3.29:1 or 4.34:1) (HALDERMAN; BIRCH, 2017). In higher gears, overdrive gear ratios ($0 < i_G < 1$) are selected to achieve higher vehicle speeds while keeping the engine speed low, promoting fuel efficiency. The detailed gear ratios for automatic transmissions are discussed in the following sections.

The total powertrain ratio i_A is the relative speed between engine output shaft

and the wheel shaft, and is given by Eq. (2)

$$i_A = i_S \cdot i_G \cdot i_E \quad . \quad (2)$$

Where i_S is the torque converter ratio, i_G is the gear ratio, i_E is the final drive ratio.

As hydrodynamic torque converters convert both rotational speed and torque, their ratio is $i_S \geq 1$.

The final drive ratios i_E can vary depending on factors such as vehicle type, performance requirements, and terrain conditions. Common ranges for different axle drives in passenger cars include approximately 3.0-5.5 for spur gear axle drive, 2.5-5.0 for bevel gear axle drive, and 5.0 for worm gear axle drive.

The maximum ratio required $i_{A,max}$ is defined by the greatest traction requirement given in the worst considered condition to move-off. The smallest powertrain ratio $i_{A,min}$ is given by operating in the fuel-efficient ranges of the engine performance map. The required maximum speed condition gives the maximum road speed ratio $i_{A(v_{max,th})}$ (NAUNHEIMER et al., 2019).

The overall gear ratio $i_{G,tot}$ of the transmission relates the largest and the smallest gear ratio (Eq. (3)):

$$i_{G,tot} = \frac{i_{G,max}}{i_{G,min}} = \frac{i_1}{i_z} \quad , \quad (3)$$

with the gears from $n = 1$ to z .

The highest gear ratio for passenger cars is, in general, fixed within the range $0.7 \leq i_z \leq 1.0$.

The $i_{G,tot}$ is influenced by several factors, including the specific power of the vehicle (in kW/t), the engine's spread, and the intended use of the vehicle. In the case of AT for passenger cars, the overall gear ratio $i_{G,tot}$ spreads into 4.5 to 10 (NAUNHEIMER et al., 2019).

The number of gears is selected based on the gear ratio steps strategy. The ratio between two sequential gears (Eq. (4)) is considered the *ratio step* φ :

$$\varphi = \frac{i_{n-1}}{i_n} \quad . \quad (4)$$

The goal is to achieve an optimal balance between power utilization, shifting frequency, and overall transmission size and weight. Increasing the number of gear ratios offer better power utilization by closely following the torque curve, but they also increase the frequency of gear shifting, the weight, the size, and add complexity to the transmission. On the other hand, fewer gear ratios lead to larger step ratios, requiring the engine to operate in less efficient ranges, resulting in significant engine RPM changes between shifts and potentially decreasing performance and fuel efficiency. Factors such as specific vehicle power, road profile, traffic conditions, and driver behavior play a role in determining the ideal gear ratios.

The progressive gear ratio step method, commonly used for passenger cars, employs the Eq. (5) by relating the base ratio change φ_1 and the progression factor φ_2 to determine the intermediate ratios:

$$i_n = i_z \cdot \varphi_1^{(z-n)} \cdot \varphi_2^{0.5(z-n)(z-n-1)} \quad (5)$$

Initial values of $1.1 \leq \varphi_1 \leq 1.7$ and $1.0 \leq \varphi_2 \leq 1.2$ are typically chosen, but further adjustment and fine-tuning are necessary to optimize the gear ratios for specific vehicles (SINGH et al., 2012; BERA, 2019).

The gear ratios of a transmission and their corresponding characteristics are typically displayed in a truth table, outlining the engagement sequence for the shift couplings. In Table 3, which is based on Figures 1 and 2 of Raghavan and Usoro (2000), the truth table for a 6-speed automatic transmission illustrates each gear ratio along with the engaged shift couplings (denoted by \otimes) and their respective ratio steps. This particular AT comprises five shift couplings, including three brakes (B_1 , B_2 , and B_3) and two clutches (C_1 and C_2). These couplings are engaged in pairs, with one clutch disengaging while the other engages, resulting in the changing of only one shift coupling from one gear to the next. The engaging sequence in this transmission follows a clutch-to-clutch pattern. This arrangement enables the transmission to operate with one reverse gear (R), three underdrive gears (1, 2, and 3), one direct gear (4), and two overdrive gears (5 and 6). The overall gear ratio is $i_{G,tot} = 6.15$.

Table 3 – Gear ratios truth table of a 6-speed transmission.

Gear	Gear Ratio	shift couplings					Ratio Step φ
		B_1	B_2	B_3	C_1	C_2	
R	-3.46	\otimes		\otimes			
1	3.94			\otimes		\otimes	-0.87
2	2.05		\otimes			\otimes	1.91
3	1.33	\otimes				\otimes	1.54
4	1.00				\otimes	\otimes	1.33
5	0.78	\otimes		\otimes			1.27
6	0.64		\otimes		\otimes		1.22

Source: Adapted from Raghavan and Usoro (2000).

The subsequent sections will delve into the technical definitions, analysis, and synthesis processes of planetary gear trains. Special attention will be given to the parameters governing the kinematic structure of these mechanisms, laying a solid foundation for the subsequent chapters, which will present methodologies and tools for discovering innovative gaps.

2.2 MECHANISM AND MACHINE SCIENCE REVIEW FOR PGTS

Mechanism and Machine Science, a field that explores the relationship between geometry, motion of machine parts, and the forces involved, is essential in the analysis and synthesis of mechanisms (MATA et al., 2016). Analysis involves evaluating existing mechanisms' ability to perform required tasks, while synthesis focuses on designing mechanisms capable of meeting those tasks. This may involve modifying existing solutions or inventing entirely new mechanisms based on new requirements and constraints. To establish a clear understanding of mechanisms and their characteristics, this thesis follows the terminology of IFToMM (STANDARDIZATION OF TERMINOLOGY, 2014; STARZHINSKY et al., 2017; ARTELT et al., 2019) and definitions from relevant publications (REULEAUX, 1876; HUNT, 1990; DAVIES, 1995b; TSAI, 2001; IONESCU, 2003; MATA et al., 2016) are briefly introduced below.

2.2.1 Concepts and Definitions

Mechanisms are represented in a motion space, where the dimension is referred as the *order of the system* (λ) or the degree of freedom of the space. It indicates the number of possible independent motions that a free body can exhibit within that space. For instance, in a 3-D space, the order of the system is $\lambda = 6$, representing three rotations and three translations. On the other hand, in a 2-D space (plane), the order of the system is $\lambda = 3$, consisting of one rotation and two translations.

A **link** or an element is defined as an individual rigid body subjected to negligible deformation. The relative motion between two links can be constrained by a specific form of connection, termed as a *coupling*. In situations where the links are in contact and exhibit passive relative motion, the coupling is classified as a *kinematic pair*. On the other hand, a coupling allowing active power transmission between the links is categorized as an *active coupling*.

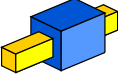

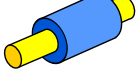

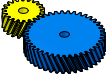

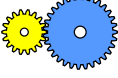

The classification of a link is based on the number of kinematic pairs it belongs to. For example, a link can be binary (belonging to two kinematic pairs), ternary (belonging to three kinematic pairs), quaternary (belonging to four kinematic pairs), and so on. Additionally, when a set of links is connected together with no relative motion, it is considered as one single link.

A **joint** is the physical representation of a kinematic pair. It restricts the relative motion between its constituent links based on the geometric characteristics of the contact. Kinematic pairs are classified as *lower pair* when the contact between links occurs on a surface, or *higher pair* when the contact occurs at a line or a point. For two links in a motion space denoted by λ , inserting a joint i between them will impose c_i *degrees of constraint* and will result in f_i *degrees of freedom* as shown in Eq. (6):

$$\lambda = c_i + f_i \quad . \quad (6)$$

The most common kinematic pairs are summarized in Table 4, presenting their classification and degrees of constraint and freedom according to the motion space.

Table 4 – Kinematic pairs and their characteristics.

Class	Pair	Drawing	Symbol	Degrees	Line (1-D)	Plane (2-D)	Space (3-D)
					$\lambda = 2$	$\lambda = 3$	$\lambda = 6$
Lower	Revolute		J_R	c_R	1	2	5
				f_R	1	1	1
	Prismatic		J_P	c_P	1	2	5
				f_P	1	1	1
	Cylindrical		J_C	c_C	0	-	4
				f_C	2	-	2
Helical		J_H	c_H	1	-	5	
			f_H	1	-	1	
Spherical		J_S	c_S	-	-	3	
			f_S	-	-	3	
Planar		J_E	c_E	-	0	3	
			f_E	-	3	3	
Higher	Helical Gear		J_G	c_G	1	1	1
				f_G	1	2	5
	Spur Gear		J_G	c_G	1	1	2
				f_G	1	2	4
	Spherical Cam		J_{C_P}	c_{C_P}	1	1	1
				f_{C_P}	1	2	5
Roller Cam		J_{C_P}	c_{C_P}	1	1	2	
			f_{C_P}	1	2	4	

Source: Author.

A set of links interconnected by joints forms a **kinematic chain (KC)**. Any subset of a kinematic chain is named a *subchain* and, if it forms a closed circuit, it is named *loop*.

The set of links that belong to a kinematic chain is named a *partition*. Each possible arrangement of the links of a partition to generate a kinematic chain is named a *variation*.

A kinematic chain is designated *fractionated* when there is a link or joint whose removal results in two separated chains (disconnected chain).

A **mechanism** can be defined as a kinematic chain that allows a controlled output motion to be generated from an input motion, where one of the links is considered fixed to the ground or reference frame. Alternatively, it can be said it is a constrained system

of bodies designed to convert motions of, and forces on, one or several bodies into motions of, and forces on, the remaining bodies.

The grounded link is named the **frame link** or fixed link, denoted as 'F', and the process of fixing different links of the same kinematic chain to obtain different mechanisms is named *kinematic inversion*. Thus, from a single partition, it is possible to create several variations, each of which allows a number of kinematic inversions equal to the number of links.

The **input link(s)**, denoted as 'IN', form joint(s) with the frame through which motion and action are transmitted to the mechanism, being referred to as *input joints*. On the other hand, the **output link(s)**, denoted as 'OUT', form joint(s) with the frame where the required motion and action intended for the mechanism are performed, being referred to as *output joints*. A kinematic chain that has all input joints defined is referred to as a *constrained kinematic chain*, as all the links perform a constrained motion when the input moves in a prescribed manner.

In general, an external source provides motion and force to the input joint(s) such as an electric motor, a hydraulic piston, a combustion engine, human action, etc., which is named an *actuator*. When one or more mechanisms are connected with actuators (and optionally sensors, controllers, etc.) in order to carry out work, it becomes a *machine*.

Thus, a **machine** can be defined as a set of interrelated movable units - *mechanisms* - with supporting structures for transmit/modify motions and forces for a suitable task (Fig. 10).

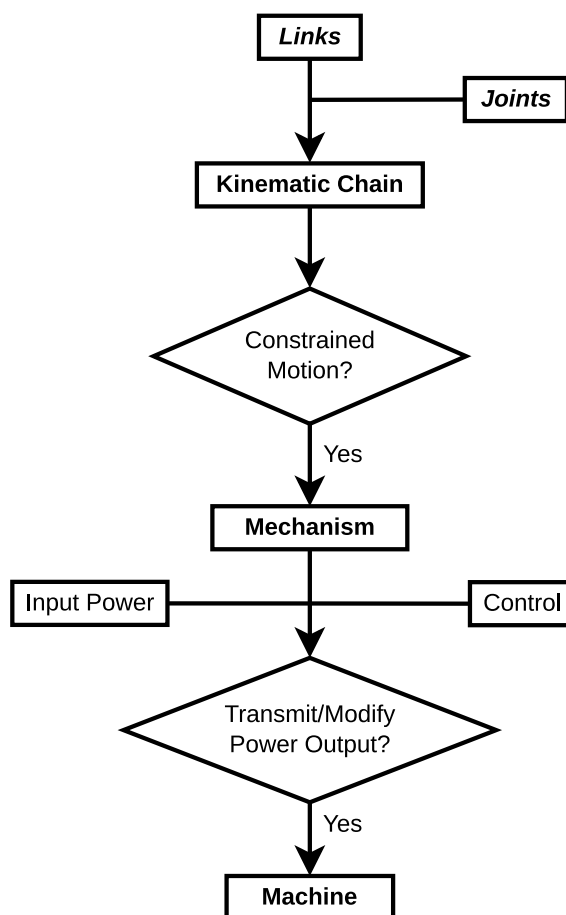

In this thesis, the conventional automatic transmissions (AT) are considered the machine, a mechanical system designed to perform specific tasks such as allowing the vehicle to move-off and providing multiple ratios by controlling the power flow between the engine and wheels. The mechanism responsible for achieving different gear ratios in AT is based on the planetary gear train, also known as epicyclic gear train (EGT), which consists of gears with mobile axes.

2.3 PLANETARY GEAR MECHANISM (PGM)

A **planetary gear mechanism (PGM)** is constituted by a kinematic chain, denoted as a planetary gear train (PGT), integrated to a frame link (housing), input and output links, and shift couplings to constrain its motion and establish a power flow. This arrangement results in a multi-degree-of-freedom mechanism capable of generating gear ratios.

PGTs belong to a special class of geared kinematic chains where the joints consist exclusively of revolute and gear pairs, enabling unlimited rotation (TSAI, 2001). A PGT is essentially composed of one or more elementary interconnected kinematic chains (HSIEH; TSAI, 1996b), referred in this research as to planetary gear sets (PGS).

Figure 10 – Overview of machine's constitution.

Source: Adapted from Yan (1998).

Within these sets, some links might be rigidly interconnected, referred to as *compound links (CL)* in this research.

Furthermore, the *shift couplings* contained in a PGM are active couplings that can be actuated to temporarily allow the transmission of torque between PGM links.

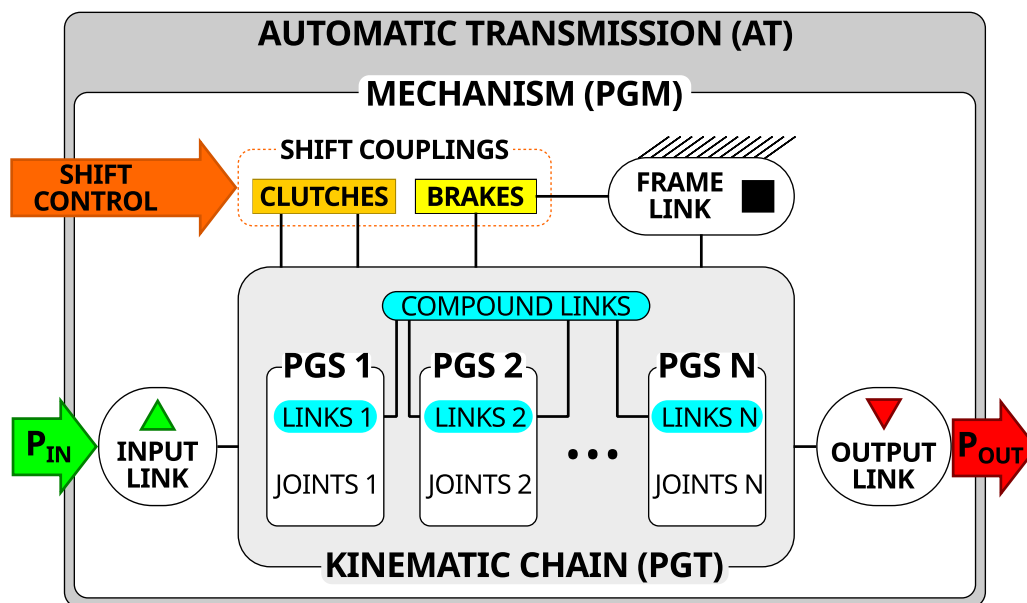

In Figure 11, an overview of a typical kinematic structure found in automatic transmissions is presented. The diagram highlights the constituent elements of its kinematic chain, providing a clear overview of its structural configuration.

As previously shown in Figure 8 and detailed in the diagram of Figure 11, an automatic transmission is characterized by multiple PGSs interconnected through compound links and shift couplings providing a multiplicity of gear ratios between input and output links when shift control actuate a combination of clutches and brakes.

There are two elementary topologies of PGSs based on the planet sets: simple and double.

A simple PGS (SPGS) consists of four basic links: a sun gear (S) and a ring gear (R) that rotate about a central stationary axis (first level), and a planet gear (P) that rotates about a second-level axis supported by a planet carrier (arm - A), maintaining a

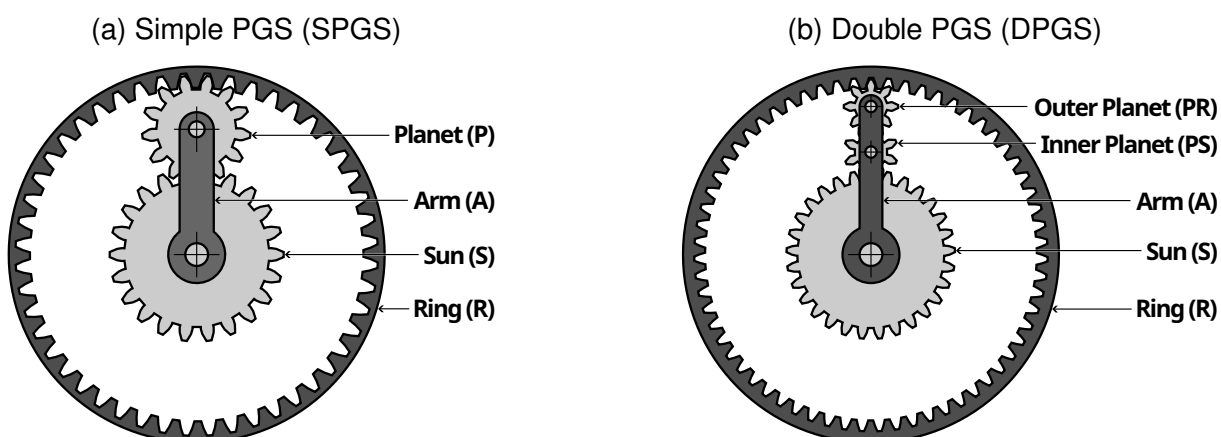

Figure 11 – Overview of a typical kinematic structure found in AT.

Source: Author.

constant center distance between the gear meshes. Since the SPGS has only one level connecting the sun and the ring, it results in opposite rotating directions between them. Figure 12a illustrates a SPGS, while Tab. 5a lists its links and Tab. 5b lists its joints.

Figure 12 – Planetary Gear Sets (PGS)

Source: Author.

A double PGS (DPGS) has two meshing planet gears connecting the sun and the ring, the inner planet (PS) and the outer planet (PR), resulting in the same direction of rotation between them. Figure 12b illustrates a DPGS, while Tab. 6a lists its links and Tab. 6b lists its joints.

The axes of rotation in PGTs are denoted by revolute joints, which are labeled with letters to distinguish their relative positions with respect to the central axis. Notably, the column 'Level' in both Table 5b and Table 6b presents revolute joints listed in alphabetical ascending order based on the level location of their axes. The letter 'a' is

Arm (carrier)	A	PR-A	revolute	b
		A-S	revolute	a

Source: Author.

assigned to joints located along the central axis, while letters 'b' or higher are designated for planet axis joints found in upper levels. Gear joints are always referred to as letter 'g' without any distinction regarding their location.

In Fig. 13, a simple PGT is illustrated and showcases the arrangement of sun gear as the input link, the planet carrier (arm) as the output link, the ring gear is a reaction link, and three equally distributed planets. By alternating the combination of input, output and reaction links, this configuration allows for various gear ratios and torque distribution capabilities, making it suitable for achieving a wide range of vehicle speed and load requirements in a compact mechanism.

The kinematic structure of PGTs can be represented in various formats to aid in the analysis and synthesis of the mechanisms. In general, the following assumptions are made for all representation methods (TSAI, 2001):

1. Due to symmetry on central axis, the PGT is represented by its upper half.
2. The multiplicity of planets is represented as a single planet for simplicity. In general, two or more planets are employed to balance the planetary structure and to increase load capacity.
3. Multiple revolute joints are represented as an equivalent set of coaxial binary revolute joints.
4. Links that are permanently connected (rigid) are represented as a single link

(compound links).

The *functional schematic representation* is a simplified cross-sectional drawing that presents only functional links as gears, shafts, and their respective couplings identified by labels. This representation aims to maintain the evident mechanism's geometry and topology, ensuring comprehensibility. Figure 14 has an example of a *schematic representation* of a simple PGT with three equally distributed planets. Figure 15 con-

Figure 14 – Schematic representation of a simple planetary gear train.

tains the *functional diagram*, also known as kinematic skeleton, representing the upper half PGM of a GM 6-speed automatic transmission composed of three SPGSs and five shift couplings comprising 3 brakes (B1, B2, B3), and 2 clutches (C1, C2). The housing (F), input (IN), and output (OUT) links, as well as the one-wheel-clutch (OWC), parallel to brake B2, are also visible. In the functional diagram, for each PGS, the multiplicity of equally distributed planets is usually represented by only one single planet (SPGS) or one double planet set (DPGS).

The *structural representation* is an abstraction of the kinematic chain relating

Figure 15 – Functional diagram of a GM 6-speed automatic transmission

Source: Author based on Singh and Olenzek (2010).

links to polygons, with vertices representing kinematic pairs. In this case, dimensions are not considered. Figure 16 is the structural representation of the SPGS (Fig. 12a) where arm (A) and ring (R) are binary links represented by lines and sun (S) and planet (P) are ternary links represented by a cross-hatched triangle. The plain vertices 'o' represent revolute pairs, whereas the solid vertices '•' denote gear pairs.

Figure 16 – Kinematic structural representation of a simple planetary gear train.

Source: Author based on Tsai (2001).

The topology of mechanism refers to the number and types of links and kinematic pairs, as well as the connection relationship between them (DING et al., 2022). A mechanism and its kinematic chain can be represented using a more abstract model known as *topological graph representation*. This approach belongs to the research field of graph theory and has been widely utilized in the analysis and synthesis of gear trains since Buchsbaum and Freudenstein (1970). Graph representations play a significant role in aiding the analysis and synthesis of PGTs and is presented in more detail in the following Section 2.3.1, as this model of representation is the primary focus of this thesis.

Furthermore, there are alternatively other representations used to study PGTs such as linkages (JOHNSON; TOWFIGH, 1967), nomographs (ESMAIL, 2013), network theory (POLDER, 1969), ports (MOLIAN, 1970), lever analogy (BENFORD; LEIS-

ING, 1981), building blocks (KOTA; CHIOU, 1992), model-based (KARHULA; NICOLAI, 2018), and zebra (S.; GHOSE, 2022), among others.

2.3.1 Graph representations

Graph theory has been utilized in the analysis of kinematic chains and mechanisms since the 1960s, when it was first introduced by Crossley (1965). This approach has greatly improved the design process by providing a more elegant and rational method, while also allowing for computer implementation, as stated by (DOBRJANSKYJ; FREUDENSTEIN, 1967). The *graph representations* have many advantages (TSAI, 2001), including the direct application of network properties to mechanisms, allowing for the analysis of kinematics, statics, and dynamics with the aid of computers. It also enables the systematic enumeration, classification, and atlas generation of mechanisms, and the generation of functional schematic and structural representations. Therefore, this research is based, but not restricted, on the graph representation of PGTs.

Buchsbaum and Freudenstein (1970) were the first to present a graph representation for the structure of geared kinematic chains including PGTs. Since then, this field was extensively discussed by researchers as summarized in these reviews (MRUTHYUNJAYA, 2003; PENNESTRI; BELFIORE, 2015; XUE et al., 2016b; JUBER et al., 2022).

In the work of Davies (1995b), a generalized model for representing mechanisms is presented through the use of a coupling graph. This model represents the relationship between links without distinguishing their mechanical nature. Two graphs can be derived based on the purpose of analysis. The motion graph represents the possible freedoms between links, and the action graph represents the constraints imposed between links. These graphs are applied by Davies (1995a) to model and analyze a two-stage turbine PGM using screw theory. A comprehensive review on Davies methods for PGT kinematic and static analysis is presented in Cazangi and Martins (2007) and Cazangi (2008).

The **conventional topological graph** of PGTs, equivalent to the motion graph, represents links as solid vertices and joints as undirected edges. Vertices are labeled or enumerated according to links. Revolute pairs are represented by solid edges labeled in alphabetic ascending order according to the level location of their axes, and gear pairs are distinguished by dashed edges. In Figure 17, the SPGS kinematic chain (Fig. 12a) is represented by its functional diagram (Fig. 17a) and its associated topological graph (Fig. 17b) evidencing two joint levels, the central axis with label 'a', and the planet (P) axis with label 'b'.

In Figure 18, the DPGS kinematic chain (Fig. 12b) is represented by its functional diagram (Fig. 18a) and its associated topological graph (Fig. 18b) evidencing three joint

Figure 17 – Simple PGS kinematic chain representations.

Source: Author.

levels, the central axis with label 'a', the inner planet (PS) axis with label 'b', and the outer planet (PR) axis with label 'c'.

Figure 18 – Double PGS kinematic chain representations.

Source: Author.

A link is referred to as the *transfer vertex* when it maintains a constant center distance between the axes of two geared links, positioning them at different levels. In the case of the simple PGS (Fig. 17), and the double PGS (Fig. 18), the arm (A) link serves as the transfer vertex. In the simple PGS, the arm (A) link rotates around the central axis (level 'a') and supports the planet axis in level 'b'. Similarly, in the double PGS, the arm (A) link rotates around the central axis (level 'a') and supports the inner planet (PS) axis in level 'b' and the outer planet (PR) in level 'c'.

In a PGT, the interconnection of n links through j joints is represented by a connected topological graph containing at least two circuits. Each *circuit* (or *loop*) is a path through existing edges starting and ending at the same vertex, without repeating any vertex. On the other hand, a *tree* is a connected graph that has no circuits. The tree

is considered a *spanning tree* if it is a subgraph of the topological graph that includes all vertices and only a subset of its edges. Specifically, the edges belonging to the spanning tree are named *branches*, and the remaining edges are named *chords*. The subgraph obtained by removing all geared edges from the topological graph of an PGT must be a tree. Any geared edge added onto the tree forms a unique circuit named the *fundamental circuit (f-circuit)*, i.e., each f-circuit is comprised by one gear pair (chord) and several revolute pairs (branches).

In order to generate a PGM, the housing or frame (F), input (IN), and output (OUT) links, as well as the joints related to shift couplings, must be incorporated into the PGT. Due to these links, a subgraph of three vertices and two revolute edges in level 'a' should be aggregated to the graph representation (Fig. 19). In this thesis, to

Figure 19 – Subgraph of vertices F, IN, and OUT to generate a PGM.

Source: Author.

enhance the readability of mechanism graphs, a slight distinction in vertex symbols is introduced for three specific links: frame (■), input (▲), and output (▼). These links can either be associated with existing kinematic chain links or included as new ones. Likewise, the addition of shift couplings (brakes and clutches) requires proper actuation and should be located in level 'a', being connected to existing level 'a' revolute joints or added as new ones between existing links.

In Figure 20, the PGM containing one SPGS is represented by its functional diagram (Fig. 20a) and its associated topological graph (Fig. 20b). The frame (F) and output (OUT) links are added as new vertices in the graph, and the input link (IN) was associated to the existing sun (S). The two clutches (C1, C2) and two brakes (B1, B2) were added as four new edges in the graph.

In Figure 21, is presented the graph representation of the GM 6-speed automatic transmission (Fig. 15) to exemplify a more complex PGM.

In Table 7, a summary of basic correspondences between mechanisms and graphs is presented.

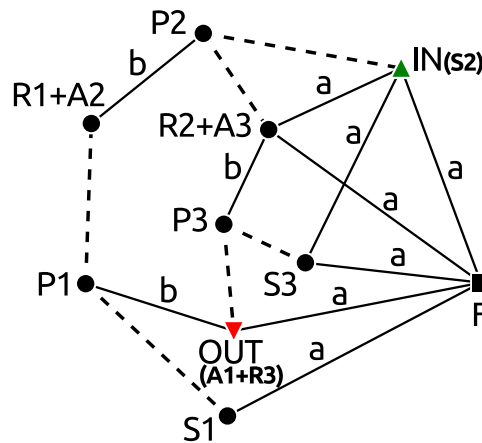

In the literature, various other graph representations for mechanisms are discussed, such as rotational and displacement graphs (FREUDENSTEIN, 1971), closed rotation and displacement graphs (RAVISANKAR; MRUTHYUNJAYA, 1985), coincident-joint graph (OLSON et al., 1991), coincident-joint graph with solid polygons to de-

note multiple joints (HSU; LAM, 1992), canonical graphs (CHATTERJEE; TSAI, 1994), graphs based on functional constraints (CASTILLO, 2002), and double bicolored graphs (DBG) (YANG et al., 2018). For a comprehensive review of graph representations for PGTs, refer to (XUE et al., 2016b).

The *matrix representation* of PGTs is an extension of the close relationship between graphs and matrices, which has greatly facilitated the computational analysis of mechanisms. The main matrix is the adjacency matrix (A), which correlates adjacent links by representing them with 1 and the others with 0, as follows:

$$A = [a_{xy}]_{n \times n} = \begin{cases} 1 & \text{if link } x \text{ is connected to link } y, \\ 0 & \text{otherwise (including } x = y), \end{cases}$$

where x is a link in row, y is a link in column and n is the total of links in the mechanism.

The incidence matrix (B) correlates links in each row with their respective incident joints in each column, as follows:

$$B = [b_{xy}]_{n \times j} = \begin{cases} 1 & \text{if link } x \text{ contains incident joint } y, \\ 0 & \text{otherwise,} \end{cases}$$

where x is a link in the row, y is a joint in column, n is the total of links and j is the total of joints in the mechanism.

Both matrices serve as the unequivocal representations of the graph; all other matrices are derivatives of these two. Operations such as contractions, expansions, and property analysis in graphs can be directly applied to matrix representations for computational analysis of mechanisms.

2.3.2 Structural Analysis

The structural analysis of planetary gear trains involves studying the interconnections and mobility of their components, with a specific focus on fundamental relationships, including degrees of freedom, number and type of links, joints, and loops, among other relevant properties. Graphs are utilized to represent the kinematic structure of PGTs, facilitating the translation of useful characteristics and properties from graphs to features of kinematic chains and mechanisms. According to [Tsai et al. \(1988\)](#), the structural analysis of the **PGM** reveals both the specific PGT utilized in the transmission and the arrangement of the shifting couplings. The following sections provide indispensable analyses to comprehend the overall functional characteristics of PGTs and **PGMs**.

2.3.2.1 Mobility Equation

The mobility M is the primary characteristic that determines the number of inputs (independent variables) required to drive the mechanism. Also named the net degree of freedom, it is defined as the sum of all degrees of freedom F of each link that composes a mechanism, moving freely in space, minus the motion constraints C imposed by the joints between them and the definition of a fixed body ([Eq. \(7\)](#)).

$$M = F - C \quad (7)$$

For two links in a motion space denoted by λ , inserting a joint i between them will impose c_i degrees of constraint and will result in f_i degrees of freedom as shown in Eq. (8):

$$\lambda = c_i + f_i \quad (8)$$

Considering a mechanism where one link is fixed and all the remaining $n-1$ links are free to move in space λ , its degree of freedom F is given by $\lambda(n-1)$. Now, inserting j joints among the links impose $C = \sum_{i=1}^j c_i$ constraints and the mobility (Eq. (7)) of the mechanism results in (Eq. (9)):

$$M = \lambda(n-1) - \sum_{i=1}^j c_i \quad (9)$$

Expressing the mobility equation in terms of degrees of freedom (Eq. (8)) results in the Grübler-Kutzbach criterion (GRÜBLER, 1917; KUTZBACH, 1929) shown in Equation (10):

$$M = \lambda(n-j-1) + \sum_{i=1}^j f_i \quad (10)$$

where λ is the motion space, n is the number of links, j is the number of joints (kinematic pairs) and f_i is the degree of freedom of the i -th joint. The Grübler criterion, as stated by Tsai (2001), holds true when the constraints imposed by the joints in a mechanism are independent and do not introduce redundant degrees of freedom. A redundant degree of freedom refers to a motion that does not affect the transfer of motion from the input to the output link of the mechanism.

The general form of the mobility equation is discussed for almost two centuries, and there are still challenges as shown in these reviews (GOGU, 2005; PENNESTRI et al., 2005; DVORNIKOV; ZHUKOV, 2022).

In PGTs, the only kinematic pairs considered are revolute and gear types. So, the total number of joints j is given by (Eq. (11)):

$$j = j_R + j_G \quad (11)$$

where j_R is the number of revolute joints and j_G is the number of gear joints in the mechanism.

Revolute joints j_R allow only one relative motion of rotation between links, independently of the motion space, resulting $f_{R,\lambda} = 1$ degree of freedom (REULEAUX, 1876).

Gear joints j_G constrain only the relative rotation between links about their own axes as a function of the transmission ratio, independently of the motion space, resulting $c_{R,\lambda} = 1$ degree of constraint (KHULIEF, 2013).

The degrees of freedom and constraints for revolute and gear joints are summarized in the Tab. 8, according to the motion space.

Table 8 – Degrees of freedom and constraints of revolute and gear joints in each motion space.

λ	j_R		j_G	
	$f_{R,\lambda}$	$c_{R,\lambda}$	$f_{G,\lambda}$	$c_{G,\lambda}$
2	1	1	1	1
3	1	2	2	1
6	1	5	5	1

Source: Author.

The mobility equation (Eq. (7)) applied to PGTs can be expressed as follows (Eq. (12)):

$$M = \lambda(n-1) - j_R \cdot c_{R,\lambda} - j_G \cdot c_{G,\lambda} \quad (12)$$

The Grübler-Kutzbach criterion (Eq. (10)) for PGTs can be written as (Eq. (13)):

$$M = \lambda(n-j-1) + j_R \cdot f_{R,\lambda} + j_G \cdot f_{G,\lambda} \quad (13)$$

The mobility of PGMs represents the motion at the input joint plus the number of shift couplings that need to be actuated to achieve a transmission ratio at the output joint. The total number of possible modes of generating a gear ratio is given by the following combination (Eq. (14)):

$$\text{Total Modes} = \binom{SC}{M-1} = \frac{SC!}{(M-1)!(SC-M+1)!} \quad (14)$$

Where SC denotes the total number of shift couplings, and M represents the mobility of the PGT.

2.3.2.2 Link Assortments

Given a PGT with \tilde{L} loops, n links, and j joints, the *Euler's equation* relates them as (Eq. (15)):

$$\tilde{L} = j - n + 2 \quad (15)$$

Considering the PGTs are always a closed-loop kinematic chains, the minimum number of joints comprising a corresponding link must be 2. On the upper side, the maximal degree p allowed for a link in a partition is limited by the number of loops (\tilde{L}) in the kinematic chain. By relating the link maximal degree and the Equation (15), it is possible to obtain (Eq. (16)):

$$p \leq \tilde{L} = L + 1 = j - n + 2 \quad (16)$$

where L is the number of fundamental loops in the graph.

The link assortments is the process of distribution of links by their degree of adjacency, generating partitions. Considering n_k the number of links with k joints, the total number of links (n) of a PGT graph can be described as (Eq. (17)):

$$n_2 + n_3 + n_4 + \dots + n_p = n \quad . \quad (17)$$

Each joint is a coupling between two links and each link n_i contains i joints, describing another relation (Eq. (18)):

$$2n_2 + 3n_3 + 4n_4 + pn_p = 2j \quad . \quad (18)$$

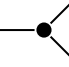

Combining both Equations (17) and (18), it is possible to identify the lower bound number of binary links n_2 as (Eq. (19)):

$$n_2 \geq 3n - 2j \quad . \quad (19)$$

Given the number of links n and joints j , all possible partitions can be determined by solving the system of equations involving Equations (17) to (19).

As explained in Section 2.2.1, it is possible to have multiple PGMs for a single partition. As an example, the GM 6-speed AT (Fig. 15) PGM partition is detailed in Table 9.

Table 9 – Link assortments of the GM 6-speed AT graph (Fig. 21).

Degree of vertex	k	Graph	Links	Link Assortment
binary	2		S1, R1+A2	$n_2 = 2$
ternary	3		OUT, P1, P2, P3, S3	$n_3 = 5$
quaternary	4		IN, R2+A3	$n_4 = 2$
quinary	5		F	$n_5 = 1$

Source: Author.

The concept of link assortments is commonly used to group PGTs into families based on the similarity of their degrees. Furthermore, the maximal degree is utilized in the synthesis equations of mechanisms to establish an upper bound for generating link assortments.

2.3.2.3 Structural Characteristics of PGTs

The topology of a mechanism is defined by its structural characteristics, relating its kinematic chain to the required functionalities. Buchsbaum and Freudenstein (1970) described a set of structural characteristics about the geared kinematic chains of PGTs based on topology graph. Subsequently, in their follow-up study (FREUDENSTEIN, 1971), it was synthesized in a set of rules as follows:

- S1. The mechanism must satisfy the general degree-of-freedom (DOF) equation represented by the Grübler-Kutzbach criterion Eq. (13).
- S2. For a PGT with n links and mobility M -DOF, the corresponding graph must have n vertices, $j_R = n - 1$ revolute edges, and $j_G = n - 1 - M$ geared edges.
- S3. The subgraph obtained by removing the geared edges must be a tree.
- S4. Each geared edge added to the tree forms a unique fundamental circuit.
- S5. The number of f-circuits (L) is equal to the number of geared edges (j_G).
- S6. Each vertex n_i must have at least one incident edge that represents a revolute pair.
- S7. The subgraphs' mobility (M') must be at least one, to avoid structures.
- S8. In each f-circuit, there is one transfer vertex, such that all revolute edges on one side of the vertex are at the same level, and all revolute edges on the other side of the vertex are at a different level.

Moreover, Tsai (2001) suggests additional structural characteristics concerning PGTs:

- S9. The torque converter, clutch controller, final reduction, and differential can be temporarily ignored for the purpose of structure synthesis.
- S10. Turning-pair edges of the same level and their end vertices form a tree.
- S11. The graph of a PGT should not contain any circuit that is made up of only geared edges to avoid complexity.
- S12. A PGT is a fractionated two-DOF mechanism. Specifically, it is made up of a one-DOF PGT supported by the housing of a transmission mechanism on a central axis.
- S13. Only coaxial links of a PGT are used as the input link (IN), output link (OUT), and shift couplings.
- S14. For a one-DOF PGT with m_r desired gear ratios, the number of coaxial links n_c (with revolute joints in level 'a') should satisfy the inequality:

$$(n_c - 1)(n_c - 2) + 1 \geq m_r \quad .$$

- S15. There shall be no redundant links (the removal of the link does not affect the mobility of the mechanism) or partially locked subchains.

The inequality in Item S14, as proposed by Tsai et al. (1988) as a necessary condition for single-DOF mechanisms, is based on two assumptions: the potential to alternate input power among coaxial links, and the permanent designation of one of the coaxial links as the output. Furthermore, this condition can be extrapolated to serve as a requisite for mechanisms with multiple degrees of freedom, as illustrated in Equation (20):

$$n_c \geq \frac{1}{2} \cdot \left(1 + \sqrt{4m_r - 3} \right) + M \quad . \quad (20)$$

Then, given the desired m_r gear ratios (including reverse), it is possible to determine the minimum number of coaxial links n_c for any mobility M .

These structural characteristics form the fundamental basis for analyzing the feasibility of PGTs through the use of graph representation.

2.3.2.4 Isomorphism in PGTs

Isomorphism refers to the property of mechanisms and graphs sharing the same topological structure (MCKAY; PIPERNO, 2014). In the context of innovation, isomorphism represents identical mechanisms or kinematic chains, which is undesirable. Detecting graph isomorphism is a critical step in the analysis and synthesis process, and various solutions have been proposed, such as methods based on string codes (YANG; LI, 2022), perimeter loops (YANG; DING, 2018), matrix operations (MUSTAFA et al., 2019a; XU et al., 2020; SUN et al., 2021), characteristic polynomials (MUSTAFA et al., 2019b), among others.

According to Tsai (2001), an ideal algorithm for detecting structural isomorphism should provide a unique, efficient, and decodable representation of kinematic chains, facilitating automated identification and storage for practical design applications. Despite the existence of several reliable solutions, researchers are continually exploring computationally agile approaches to expedite the analysis process.

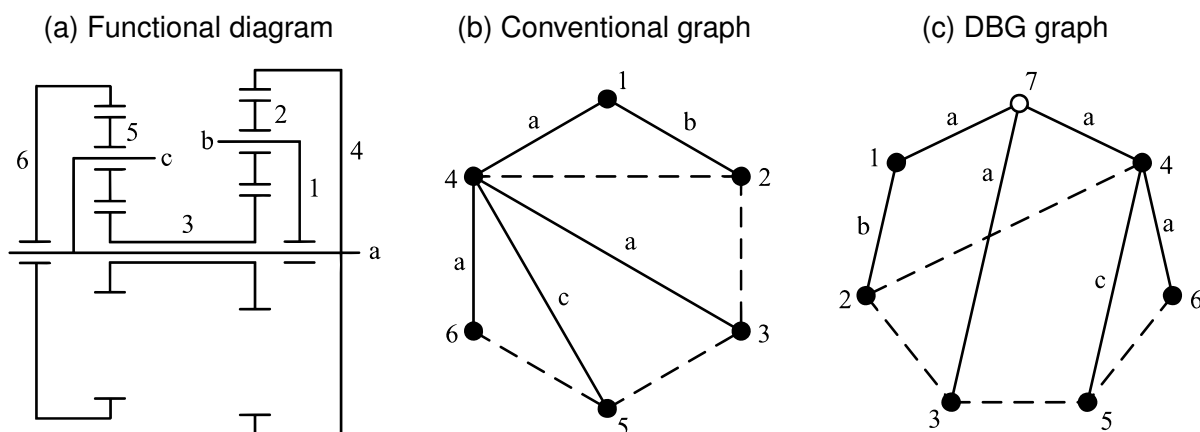

Pseudoisomorphism, another challenge in the comparative analysis of PGTs (HSU; LAM, 1992), refers to the situation where PGTs are structurally and mathematically non-isomorphic graphs but are functionally isomorphic. This phenomenon often arises when multiple links are coaxial, meaning they rotate among themselves sharing the same axis, resulting in circuits with edges solely in level 'a' in the graph, indicating a circular dependency. These multiple joints give rise to numerous constructive combinations of mechanisms that are structurally different but functionally identical. Chatterjee and Tsai (1994) proposed a canonical graph to deal with pseudoisomorphic topologies.

Yang et al. (2018) and Yang and Ding (2019) introduced a double bicolor graph (DBG) representation aiming to reduce the number of potential pseudoisomorphisms resulting from coaxial revolute joints. In their graph model, fictitious multiple joints (hollow vertices 'o') are introduced as references at each axis location with a multiplicity of links (solid vertices '•') rotating among themselves. The original revolute joints are removed and substituted by edges between the hollow vertices and the related links. This process aids in identify and reduce the number of isomorphisms and pseudoisomorphisms during synthesis process. The graph attend to the fundamental structural characteristics rules similarly to the conventional topological graph, with the following differences: gear edges cannot connect to hollow vertices; revolute edges incident to hollow vertices must be at the same level; the degree 'k' of the hollow vertex is equivalent to 'k-1'

revolute pairs; graphs with different numbers of hollow vertices are non-isomorphic; and graphs containing hollow vertices of different degrees are non-isomorphic; the mobility of DGB graph is equal the mobility of PGT plus the number of hollow vertices. In this graph model, only the PGT kinematic chain is considered.

An illustration of the application of the **DBG** graph model to the well-known Simpson PGT is presented in **Figure 22**. The functional diagram (**Fig. 22a**) is followed by its corresponding conventional topological graph (**Fig. 22b**), and the double bicolored graph (DBG) representation (**Fig. 22c**). In this case, the DBG graph comprises the hollow vertex '7' as a multiple joint (*MJ*) with degree $d = 3$ representing the coaxial links (1, 3, 4, 6) rotating in the central axis (level 'a').

Figure 22 – Representations of a Simpson PGT.

Source: Adapted from [Yang et al. \(2018\)](#).

In this thesis, the DBG graph is used to model the PGTs in parallel with the conventional topological graph model, which is employed to represent **PGMs**.

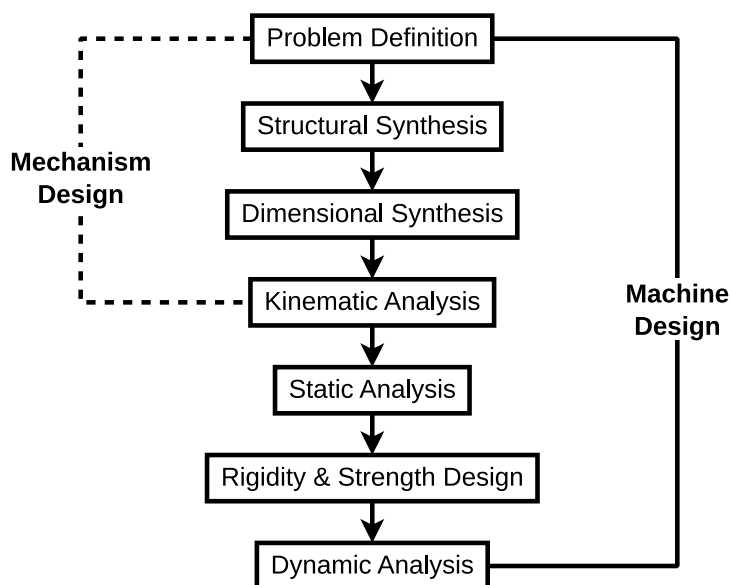

2.4 PGT DESIGN

Machine design is a logical process that demands high creative and technical skills to solve a particular problem surrounded by engineering constraints. It can be divided in 4 major design phases: Informational, Conceptual, Detailing and Product ([YAN, 1998](#); [TSAI, 2001](#); [NORTON, 2006](#); [PAHL et al., 2007](#); [BACK et al., 2008](#)). The *Informational* phase comprises to identify customer's needs and translate them into engineering specifications for the machine to be designed. The *Conceptual* is the creativity phase, where a pool of design alternatives are generated, evaluated and the most promising concept is selected. The *Detailing* phase comprises engineering studies as design analysis, optimization, and simulation to detail function, shape, material and production methods. The *Product* is the last phase, comprising construction of prototypes, testing and validation of the detailed design for documentation and manufacturing of the final product.

Decisions made in the two initial design phases, Informational and Conceptual, significantly influence the manufacturing cost of the final product and rely on the designer's intuition, ingenuity, and experience. For Yan (1998), the Conceptual phase is the most difficult and least understood step in the design process due to its requirements for creativity and knowledge. It is also in the Conceptual phase that mechanisms are designed.

Mechanism design is described by Yan (1998) as the generation or selection of a particular type of mechanism, the determination of the required numbers and types of elements and joints, and the derivations of geometric dimensions of elements between joints to achieve the desired requirements of the constrained motion (Fig. 23).

Figure 23 – Mechanism and Machine design.

Source: Yan (1998).

A typical mechanism design process involves (HARTENBERG; DENAVIT, 1964; YAN, 1998; TSAI, 2001; MATA et al., 2016):

- KINEMATIC SYNTHESIS: design of a new mechanism that satisfies required motion characteristics from the input to output links to perform a task. It is subdivided in two main phases:
 - **Structural Synthesis:** enumeration of all feasible kinematic structures or linkage topologies for a given number of degrees of freedom, number of links, and type of joints. It is comprised by two steps:
 - * *Number Synthesis:* determination of the number of links, joints and their interconnection needed to achieve a given mobility of the desired mechanism.
 - * *Type Synthesis:* determination of specific type of kinematic pairs to meet the functional requirements of the mechanism. Other considera-

tions such as materials, manufacturing processes, and cost also can influence in the type synthesis.

- **Dimensional Synthesis:** determination of appropriate dimensions of links as lengths, angles, and proportions for the mechanism to perform the desired motion.
- **KINEMATIC ANALYSIS:** study of relative motions associated with the links of a mechanism such as displacement, velocity, acceleration, etc., given an input motion and joint constraints.

The scope of this thesis is to investigate the structural characteristics of **PGMs** aiming to identify potential innovative gaps in design requirements for assisting designers in the structural synthesis of new mechanisms.

2.4.1 PGM Structural Synthesis

As stated in [Chapter 1](#), it is possible to distinguish **PGM** design methodologies in two main approaches ([FREUDENSTEIN; MAKI, 1979](#)): *atlases of mechanisms* grouped according to function and *abstract representation* of the structure of mechanisms.

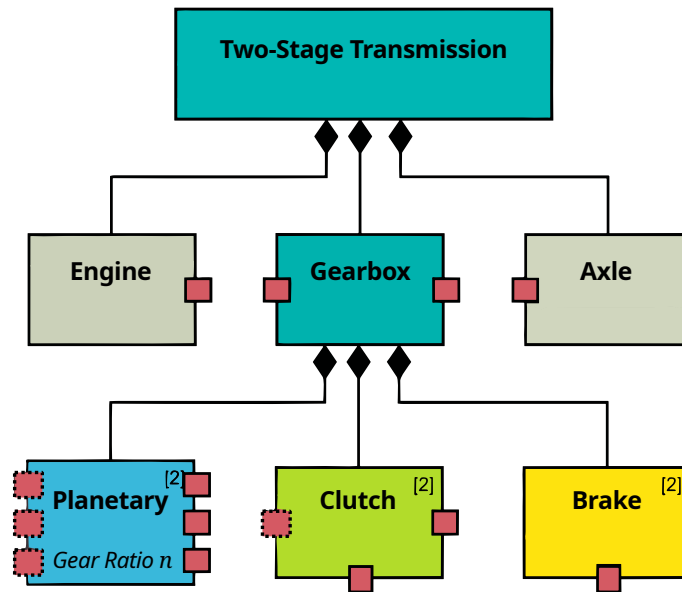

2.4.1.1 PGM Atlas-based Methodologies

The *atlases-based methodologies* represent an approach to mechanism design that involves utilizing a library of elementary mechanisms, known as building blocks, which are categorized based on their function ([KOTA; CHIOU, 1992](#); [SUBRAMANIAN; WANG, 1995](#); [YAN; OU, 2005](#); [HAN; LEE, 2006](#); [OU et al., 2010](#); [HU et al., 2017](#)). These building blocks serve as design concepts with rules rather than specific structural forms. To create new mechanisms, at least two building blocks are combined, and their parameters are adjusted to meet the desired task.

[Karhula and Nicolai \(2018\)](#) presents a computational design synthesis using a block-based approach for **PGMs**. Design requirements are selected from a patent survey, and a declarative design model ([Fig. 24](#)) with constraints is used to generate multiple mechanism candidates. Three new 4-speed **PGMs** were discovered. In ([KARHULA et al., 2019](#)), the block-based method was extended considering symmetry breaking to exhaustively synthesize 2-, 3-, and 4-speed PGT designs ([Fig. 25](#)), resulting in new topologies. However, the method is computationally demanding.

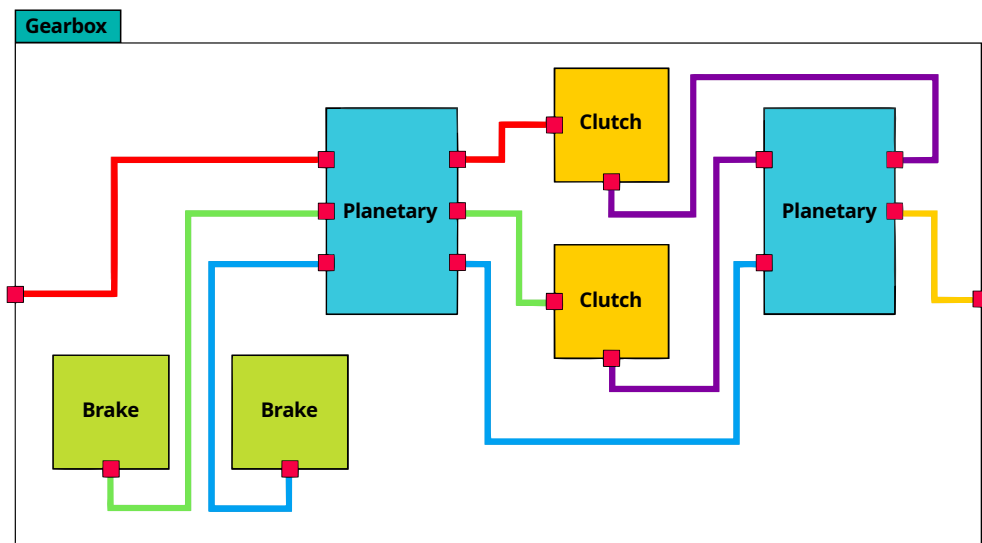

In a recent study conducted by [Köller and Schmitz \(2022\)](#), an automated method for the synthesis of transmission topologies and the pre-design of gears for electric vehicles was introduced. Their method utilizes a library of topologies and employs a multi-criteria evaluation to optimize and rank the solutions ([Fig. 26](#)). The methodology was applied using a BMW i3 passenger car and a 40-ton truck as reference data to validate the model and reach new topologies.

Figure 25 – Topology representation of a 4-speed PGT

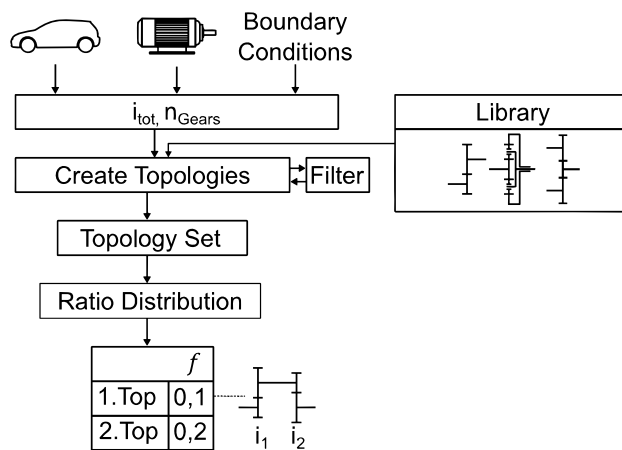

Source: Karhula et al. (2019).

2.4.1.2 PGM Abstraction-based Methodologies

The *abstraction-based methodologies* use representations such as equations, matrices, and graphs to design mechanisms. These considered creative design methodologies, also known as *enumeration-based methodologies*, systematically enumerate all possible kinematic structures of the same mobility, type of motion (planar, spatial, etc.), and complexity using graph theory, combinatorial analysis, and computer algorithms. Each kinematic structure is evaluated based on a subset of design specifications to select the most suitable mechanisms for further analyses, optimization, and detailing.

Figure 26 – Overview of a library based topology synthesis process for EVs.

Source: Köller and Schmitz (2022).

Dobrzanskyj and Freudenstein (1967) proposed a systematic approach for enumeration of mechanisms using graph theory by separating the kinematic structure from functional considerations. Their approach was a significant development in the structural synthesis phase of the mechanism design process, and comprehensive reviews can be found in (YAN, 1992; TSAI, 2001; MRUTHYUNJAYA, 2003; SIMONI et al., 2011; YAN; CHIU, 2015; MURAI, 2019; DING et al., 2022).

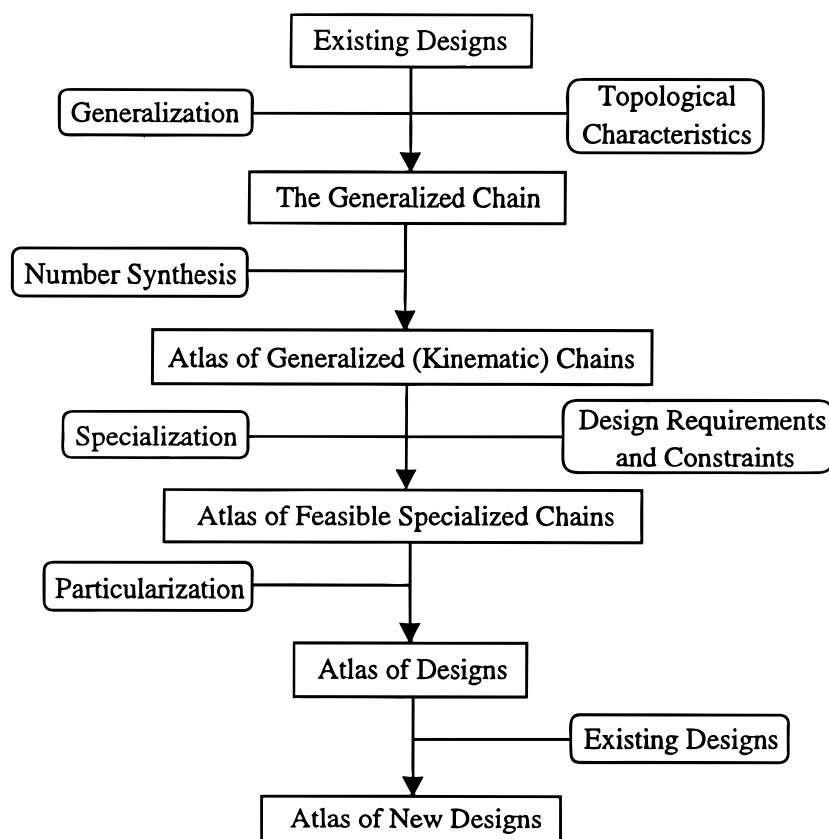

In the structural synthesis of PGTs, graphs have significantly enhanced the capacity for abstraction in the design process, and their use has been extensively investigated. To achieve a feasible topology, any graph representing a PGT must comply with the structural characteristics detailed in Section 2.3.2.3. Buchsbaum and Freudenstein (1970) by separating the kinematic structure from functional considerations. Subsequently, Freudenstein (1971) presented the concepts of rotation and displacement graphs. The rotation graph is associated with the rotational displacement equations of a PGT based on the transfer vertex (arm link) and is derived from the topological graph by omitting revolute edges and transfer vertices. Then, each gear pair is labeled with the respective transfer vertex identifier. In contrast, the displacement graph pertains to the linear displacement equations of a PGT, depending on the center distance between gear pair axes. The displacement graph is generated from the rotation graph, with vertices labeled based on the edge pair levels connecting them to transfer vertices in the f -circuits where they reside. According to the review of Shanmukhasundaram et al. (2021), the structural synthesis of PGTs centers on enumerating all non-isomorphic displacement graphs given a specific number of links and degrees of freedom. The synthesis is categorized into three primary stages. Firstly, candidate PGT kinematic chains are based on graphs derived from existing PGTs. Then, isomorphism detection is performed to discard graphs with duplicate kinematic structures. Finally, non-isomorphic graphs are assessed to remove those corresponding to degenerate or rigid PGT chains (ALI et al.,

2022), which are subchains exhibiting zero DOF. Two main methodologies have been identified: generating all rotation graphs first and then producing displacement graphs for each non-isomorphic rotation graph, or directly enumerating all displacement graphs from a set of parent graphs. In both methodologies, an isomorphism test is imperative.

Various synthesis techniques for PGTs, such as the parent graph (BUCHSBAUM; FREUDENSTEIN, 1970; DING, 2015; SHANMUKHASUNDARAM et al., 2019), genetic graph (TSAI, 1987), and acyclic graph (HSU; HSU, 2000), have been adopted. Irrespective of the method chosen, the inventive design process typically relies on the intersection between a generalized atlas of topology candidates and design specifications to generate feasible mechanisms.

An example of a creative design methodology for structural synthesis is illustrated in Figure 27.

Figure 27 – Flowchart of a creative design methodology for structural synthesis.

Source: Yan (1998).

In order to transform a PGT into a PGM, it is required to integrate the frame (F), input (IN), and output (OUT) links, as well as to identify the shift couplings essential for actuation. This procedure, referred to as *configuration synthesis*, involves making decisions about the positioning of each link, determining the number and location of shift couplings, and specifying their types. Generally, the most viable PGT kinematic structure (topology) from the enumeration are selected for further investigation. An ex-

haustive search method is subsequently utilized to generate all possible configurations of the mechanisms. Later on, three main criteria are used to evaluate these mechanisms: a kinematic analysis, which determines the number of unique gear ratios; an assemblability analysis, ensuring the absence of topological interferences; and a feasibility analysis, ensuring alignment with design specifications. For the configuration synthesis, a range of methods have been employed, such as coded sketches (HWANG; HUANG, 2011), the lever method (ROSS; ROUTE, 1991; HO; HWANG, 2020; KE et al., 2021), matrix-based strategies (DONG et al., 2023), and even relying on the expertise of designers (HWANG; HUANG, 2005; DING et al., 2020).

When it comes to mechanism design, each structural synthesis methodology has its own set of advantages and disadvantages. However, they all share core steps in the design process. Here are the key steps that are consistent across these methodologies:

1. **Define design specifications** by encompassing functional and structural requirements, design constraints, and relevant characteristics based on both customer needs and existing design analyses. The fundamental set of structural characteristics, including mobility, spatial order, and the number of links or independent loops, serve as the basis for enumeration. These values are usually derived from an existing design chosen as a reference benchmark. Any supplementary features, requirements, or constraints are then regarded as selection criteria for further feasibility evaluations.
2. **Formulate link assortments** by allocating the kinematic pairs among the links. Structural characteristics and design constraints are used to exclude non-viable partitions.
3. **Enumerate the kinematic chains** by generating all variations for each viable link assortment. Unviable kinematic chains are excluded, specifically those that are *degenerated* by being fractionated or having null mobility subchains ($M' = 0$), and those that are *isomorphisms* by having identical kinematic structures.
4. **Generate mechanisms** designs by:
 - (a) Determine the *fixed link* for each feasible kinematic chain, thus generating all kinematic inversions.
 - (b) Specify the *input* and *output links*, based on functional requirements translated to the mechanism's structural characteristics;
 - (c) Specify the *shift couplings*, detailing their quantity, type, and placement.
5. **Eliminate potential isomorphisms and pseudoisomorphisms.**
6. Compare the generated mechanisms against existing designs to **discover innovation.**

From the preceding discussion, the significance of design specifications and structural characteristics throughout each step of the structural synthesis of mechanisms becomes evident. It is noteworthy that this procedure exhibits a combinatorial nature, leading to an exponential growth in the generation of solution candidates. Design specifications are pivotal in filtering out and discarding non-viable candidates. The primary challenge lies in determining requirements towards innovation that can effectively reduce unnecessary enumerations, minimize computational effort, and improve solution quality.

2.4.2 Design specifications

Design specifications, the detailed written descriptions of the mechanism, are obtained from a variety of sources such as customers needs, commercial products, academic publications, patent databases, among others.

A survey of existing designs in commercial products and an exhaustive search of patents is the primary step conducted by [Yan \(1998\)](#) to determine design specifications and deduce the minimal set of structural characteristics essential for enumeration. A transformation of functional requirements from customer needs into structural characteristics is proposed by [Tsai \(2001\)](#). In the mechanism design methodology presented by [Murai \(2019\)](#), based on previous studies ([MURAI et al., 2013](#); [MURAI et al., 2015](#)), a state-of-the-art survey was initiated based on searches in commercial, academic, and patent domains for developing stitching devices. They introduced four structural characteristics and one structural requirement to help designers in the selection of enumerated kinematic chains. At the Laboratory of Applied Robotics Prof. Raul Guenther - LAR ([LAR, 2018](#)), where the author of this thesis is affiliated, a methodology for patent surveys on automotive mechanisms was presented by [Hoeltgebaum et al. \(2016b\)](#). Despite being tailored for mechanisms enumeration, the approach predominantly relies on subjective assessments and expertise, possibly overlooking a diverse analysis of features. Consequently, the depth and effectiveness of the analysis may be limited by the narrow scope of features considered by the design team.

Focusing on determining PGT design specifications, [Karhula and Nicolai \(2018\)](#) conducted an assessment of 1022 patented automatic transmissions. Block models were employed, as described earlier, to delineate a technological boundary based on the complexity and capability of the mechanisms, as illustrated in [Figure 28](#). Through their analysis, an innovation opportunity was identified in the domain of four-speed transmissions characterized by a complexity level of 8 (sum of gear contacts and shift couplings). Consequently, an exhaustive synthesis was applied, resulting in the proposal of three novel designs. The modeling of PGTs through the use of topological graphs was criticized by the authors, asserting that such representation does not include clutches and brakes. This perspective holds merit since topological graphs, as

commonly presented in the literature, predominantly represent and synthesize only the kinematic chains of the mechanisms, which inherently exclude the shift couplings. *However, in this thesis, topological graphs are applied to represent the entire mechanism, including the shifting couplings.* These couplings are regarded as revolute joints between link pairs. Subsequent analyses, as presented in [Chapter 3](#), determine whether these are genuinely integrated actuators at the revolute joints or only actuators.

Figure 28 – Patent survey and technological boundary.

Source: [Karhula and Nicolai \(2018\)](#).

In a distinct study examining 673 patents to delve into the design specifications of PGTs used in existing AT designs, [Ding and Cai \(2019\)](#) employed double bicolored graphs for model representation. This approach identified 274 distinct topologies, which were further classified into 67 basic graphs (without differentiation of joint types). These graphs were sorted into 13 groups based on the mobility of the DBG and the adjacency degree of the hollow vertex. Upon analysis, certain characteristics of PGTs were observed: a range of 6 to 14 links, 4 to 9 coaxial links (level 'a'), a mobility ranging from 1 to 4, 2 to 6 gear rows, a singular input link per AT, and recommendable fewer than 4 engaging shift couplings for 2 or 3-DOF PGTs. Despite the extensive preliminary work cited, the authors proposed a methodology for deriving new PGT configurations based on basic graphs, with the intent to enhance the likelihood of innovation. This work results in 9 new DBG topologies with potential to numerous mechanisms. However, the invested research effort in patent analysis was utilized only to support decisions taken along the proposed synthesis process rather than to directly inform design specifications, optimizing the domain for an innovation-focused development.

From an industrial perspective, General Motors has developed hundreds of novel

architectures for multi-speed AT over recent decades, leading to designs that have been widely produced (RAGHAVAN, 2011). These achievements were result of an algebraic procedure rooted in the methodology of Hsieh and Tsai (1996a), which incorporates graph-based enumeration and transmission powerflow to complement traditional design approaches. This procedure was employed to synthesize AT and electrically variable transmissions (EVTs) with three PGSs and six or seven shift couplings, resulting in 8-speed transmissions (RAGHAVAN et al., 2007). Extensions to the lever analogy method (BENFORD; LEISING, 1981) for PGSs, including negative lever ratios, are presented by Raghavan (2010). Discussions on the utilization of long pinion (compound planets) for alternative AT architectures are provided in Raghavan (2013, 2018). Furthermore, the algebraic procedure was applied to produce AT and EVT with four PGSs and five or six shift couplings, achieving eight or more forward speed ratios and a reverse ratio; this led to the introduction of the GM 8L90 model (RAGHAVAN, 2015; HART, 2014). Based on the General Motors researches, a range of selection criteria for AT topology can be summarized as:

- *Structural Requirements:*
 - Reduction in component count
 - Minimization of active shift couplings
 - Maximization of speed ratios
 - Emphasis on simple PGS
 - Maximization of input clutches
 - Reduction in spin losses (open actuators)
 - Accessibility of shift couplings to hydraulic circuitry
 - Requirement for a planar graph for feasibility
 - Ensuring uniqueness by checking isomorphisms
- *Functional Requirements:*
 - Achieving a wider ratio spread
 - Prioritizing single transition clutching
 - Inclusion of direct drive
 - Adherence to progressive ratio steps
- *Technical Requirements:*
 - Evaluation of both quantitative and qualitative measures of perceived quality in areas such as safety, dependability, reliability, cost, efficiency, performance, comfort, payload, excitement, noise reduction, compactness, and delivery timing for each candidate powerflow to determine the optimal selection for a range of vehicle applications.

Throughout this thesis, efforts are directed towards improving the challenges previously mentioned by proposing a process for a state-of-the-art survey and analysis of mechanisms, driven to the discovery of potential innovative design requirements. Emphasis is placed on the analysis of patent databases, though the scope is not limited exclusively to them.

2.5 CHAPTER HIGHLIGHTS

In [Chapter 2](#), a detailed review of automotive automatic transmissions for passenger cars employing planetary gear trains is presented. Emphasis is placed on elucidating the kinematic structure of such mechanisms using graph representation and on understanding their associated characteristics. This review enables the comprehensive analysis of a wide collection of mechanisms and the examination of their design specifications. The ultimate objective is to assist transmission design engineers in identifying potential innovative requirements for the synthesis process within the domain of automotive AT design.

3 PGM MODELING REVISED AND NEW METRICS

Planetary gear mechanisms (PGMs), based on the structural characteristics of geared kinematics chains enumerated in [Section 2.3.2.3](#), are expected to adhere to the Grübler-Kutzbach general mobility equation ([Eq. \(13\)](#)). This requirement has been followed in various studies on mechanism synthesis, including works by ([RAVISANKAR; MRUTHYUNJAYA, 1985](#); [TSAI, 2001](#); [CAZANGI; MARTINS, 2007](#); [KHULIEF, 2013](#); [SHANMUKHASUNDARAM et al., 2021](#); [DING et al., 2022](#)).

However, it is essential to acknowledge that applying the general mobility equation to the topological graph of PGMs may present limitations due to the topological complexities that arise when active couplings, such as shift couplings, are incorporated into the PGT to generate the PGM. A revision in the graph model representation is proposed to attend to the research demands, giving rise to redundant and virtual constraints in the PGMs' graph representation. Case studies are presented to demonstrate these constraints, which are further considered for the revision of the general mobility equation accordingly.

Additionally, this chapter delves into the complex structural characteristics of PGMs. A discussion is instigated, and novel metrics are proposed to critically assess their performance according to topological characteristics. The complexity and capability metrics for mechanisms, including PGMs, are explored and presented to characterize technological performance indexes for innovation.

3.1 REVISION OF THE PGM GRAPH MODEL

In this research, attention is particularly given to an in-depth study of the topology of AT to compare their mechanisms and identify potential characteristics relevant to innovative design requirements.

As mentioned in [Section 2.3.2](#), the PGM is usually a fractioned mechanism encompassing two degrees of freedom, being a one-DOF PGT supported by the housing of a transmission mechanism on a central axis. The ATs are actuated through an input joint and shift couplings to obtain the possible gear ratios. These active couplings impose additional constraints to those set by the kinematic pairs of the PGT, enabling torque transmission between the links to establish the power flow. Typically, for each configuration of active shift couplings that yields a power flow, the AT is recognized as a distinct PGM. In this regard, the edges of the topological graphs exhibited in [Section 2.3.1](#) only represent the kinematic pairs of the mechanism, such as gear and revolute joints, without considering active couplings.

Shift couplings can be placed between any two links that revolve around the PGT's central axis, at level 'a'. There are two potential scenarios for allocating shift couplings:

1. Between links directly connected by a revolute joint, as a parallel coupling.
2. Between links not directly connected by a revolute joint, thereby working as a novel direct coupling.

In scenario one, the shift coupling is represented in the topological graph through the parallel revolute joint edge. However, in scenario two, the shift coupling is not included in the topological graph as there is no kinematic pair between the links.

One of the objectives of this research is the comprehensive analysis and comparison of the kinematic structure (topology) of each AT, representing them as unique PGM embodiments comprising all their couplings. To this end, all the shift couplings existing in the PGM will be assumed to have revolute joints in parallel and represented as edges in the topological graph.

However, by considering this hypothesis, a revision of the general mobility equation is necessary in order to avoid possible overconstraint conditions caused by redundancy among the kinematic pairs in PGMs. This revision is discussed through the presentation of case studies in the following section.

3.1.1 PGM Case Studies

In this section, four PGMs are depicted as case studies and their mobility is analyzed using the Grübler-Kutzbach criterion (Eq. (13)), ordered by increasing complexity. The results are discussed on a case-by-case basis to provide clarity on the mobility calculation for each topology.

3.1.1.1 Case 1: Simple PGT with 2 brakes

This PGM case refers to the simple PGT illustrated in Figure 29a, comprising:

- PGT:
 - one SPGS
 - no compound links
- PGM:
 - housing (F, ■)
 - input link (▲) in the Sun (S)
 - output link (▼) in the Ring (R) or the Arm (A)
 - two shift couplings:
 - * two brakes (B1 and B2)

The PGM has a total of $n = 5$ links, $j = 6$ joints ($j_R = 4$ revolute and $j_G = 2$ gear joints), and 2 fundamental circuits as shown in the graph of Figure 29b. Considering

$\lambda = 3$, the mobility of this PGM is calculated as follows (Eq. (21)):

$$M = 3(5 - 6 - 1) + 4 \cdot 1 + 2 \cdot 2 = 2 \text{ DOFs} \quad (21)$$

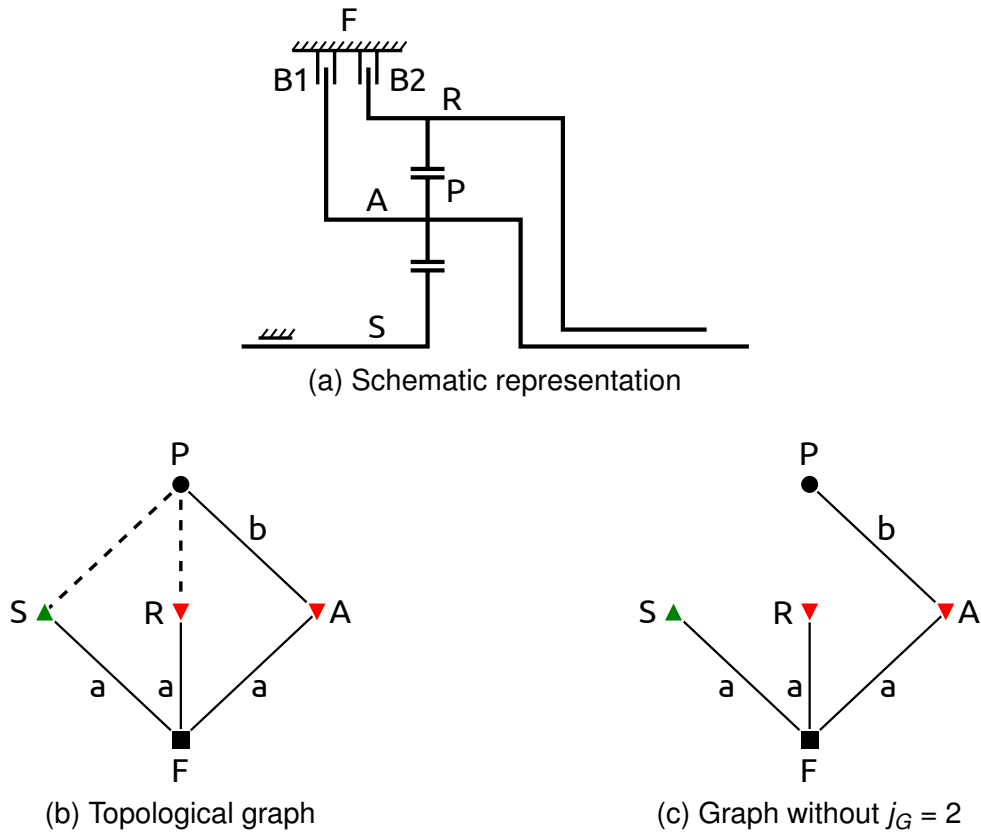

Figure 29 – Case 1: Simple PGT with 2 brakes

The obtained result of two DOFs is correct, comprising 1 DOF for the input rotation in the Sun, and the remaining 1 DOF associated with the actuation of one brake to create power flow to the selected output link. This is consistent with the structural characteristic of a fundamental circuit existing for each gear pair. The removal of the $j_G = 2$ gear pairs from the graph in Figure 29b results in a tree, as shown in Figure 29c.

3.1.1.2 Case 2: Simple PGT with 2 brakes and 1 clutch

This PGM, illustrated in Figure 30a, is a variation of the previous case (Section 3.1.1.1) by the addition of a clutch between links A and R for the direct gear ratio. It comprises:

- PGT:
 - one SPGS
 - no compound links
- PGM:
 - housing (F, ■)

- input link (\blacktriangle) in the Sun (S)
- output link (\blacktriangledown) in the Ring (R) or the Arm (A)
- three shift couplings:
 - * two brakes (B1 and B2)
 - * one clutch (C1)

The PGM has a total of $n = 5$ links, $j = 7$ joints ($j_R = 5$ revolute and $j_G = 2$ gear joints), and 3 fundamental circuits as shown in the graph of Figure 30b. Considering $\lambda = 3$, the mobility of the PGM is calculated as follows (Eq. (22)):

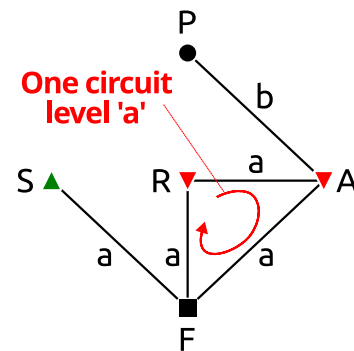

$$M = 3(5 - 7 - 1) + 5 \cdot 1 + 2 \cdot 2 = 0 \text{ DOF.} \quad (22)$$

(a) Schematic representation

(b) Topological graph

(c) Graph without $j_G = 2$

Figure 30 – Case 2: Simple PGT with 2 brakes and 1 clutch

The obtained result of zero degrees of freedom (DOF) is incorrect, as the expected mobility should be 2 DOF, comprising 1 DOF for the input rotation in the Sun, and the remaining 1 DOF associated with the actuation of 1 shift coupling to create power flow between input link and the selected output link. The inclusion of the clutch (C1) between links A and R, which already have the necessary structural constraints, resulted in redundant constraints, leading to an additional DOF in the mechanism. This situation violates the structural characteristic of existing a fundamental circuit for each pair of gears and can be identified by removing all gear pairs from the graph (Fig. 30b), resulting in a still connected graph as seen in Figure 30c when it should be a tree. The

remaining circuit is formed only by revolute joints at level 'a' as follows: B1:F-A, C1:A-R, B2:R-F.

3.1.1.3 Case 3: Simple PGT with 2 brakes, 2 clutches and output link

In this case, illustrated in [Figure 31a](#), the previous PGM of [Section 3.1.1.1](#) received the addition of an output link (OUT) and two clutches (C1 and C2). It comprises:

- PGT:
 - one SPGS
 - no compound links
- PGM:
 - housing (F, ■)
 - input link (▲) in the Sun (S)
 - output link (OUT, ▼)
 - four shift couplings:
 - * two brakes (B1 and B2)
 - * two clutches (C1 and C2)

The PGM has a total of $n = 6$ links, $j = 9$ joints ($j_R = 7$ revolute and $j_G = 2$ gear joints), and 4 fundamental circuits as shown in the graph of [Figure 31b](#). Considering $\lambda = 3$, the mobility of the PGM is calculated as follows ([Eq. \(23\)](#)):

$$M = 3(6 - 9 - 1) + 7 \cdot 1 + 2 \cdot 2 = -1 \text{ DOF.} \quad (23)$$

The obtained result of one negative DOF is incorrect, as the expected mobility should be 3 DOF, comprising 1 DOF for the input rotation in the Sun, and the remaining 2 DOFs are associated with the actuation of 2 shifting elements to create power flow between input and output links. The inclusion of the output link (OUT) with clutches C1 and C2 to select the output rotation resulted in two circuits formed only by revolute joints at level 'a': B1:F-A, C1:A-OUT, a:OUT-F and B2:F-R, C2:R-OUT, a:OUT-F. As explained in the previous [Section 3.1.1.2](#), this situation violates the structural characteristic of existing a fundamental circuit for each gear pair and can be identified by removing all gear pairs from the graph ([Fig. 31b](#)), resulting in a still connected graph as seen in [Figure 31c](#).

Incorporating a shift coupling between coaxial links leads to the formation of a redundant circuit, violating the structural characteristics of the mechanism. However, this type of circuit can be inherent in the topology of PGMs and should be considered in the mobility equation by including their respective redundant joints.

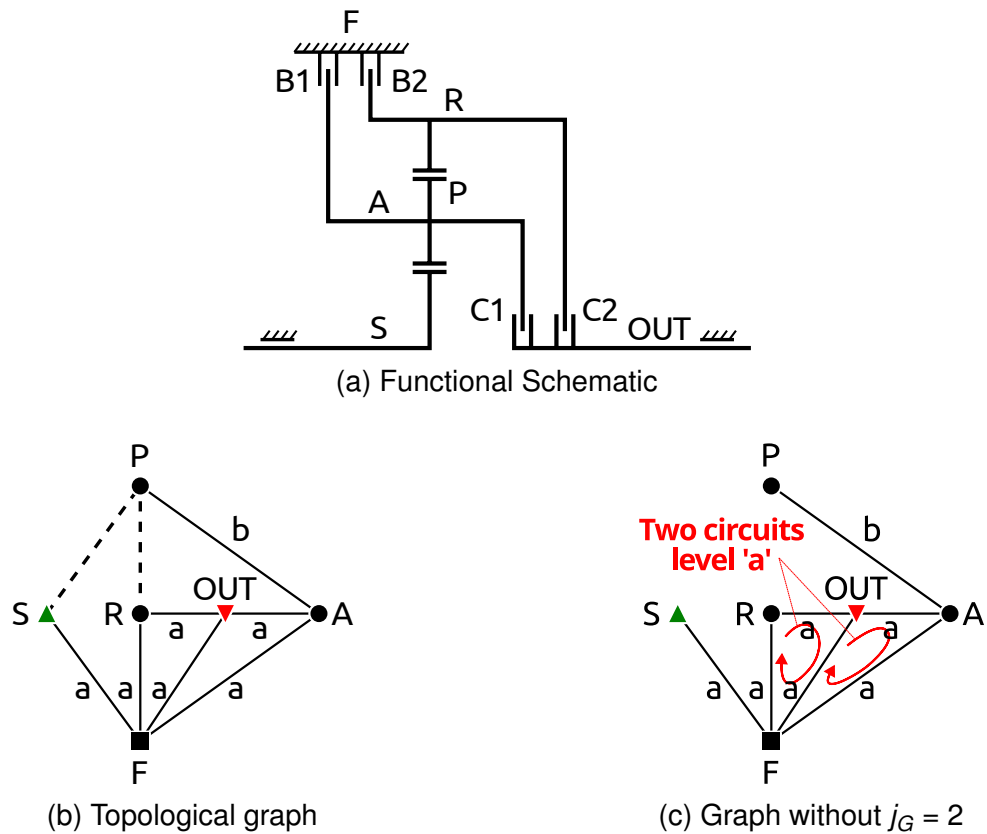

Figure 31 – Case 3: Simple PGT with 2 brakes, 2 clutches and output link

3.1.1.4 Case 4: GM 6-speed automatic transmission

The GM 6T40 (SINGH; OLENZEK, 2010), illustrated in Figure 32a, is a transversal commercial 6-speed automatic transmission model studied in this case. It comprises:

- PGT:
 - three SPGS
 - three compound links:
 - * A1;R3
 - * R1;A2
 - * R2;A3
- PGM:
 - housing (F, ■)
 - input link (IN, ▲) in the Sun (S2)
 - output link (OUT, ▼) in compound link (A1;R3)
 - five shift couplings:
 - * three brakes (B1, B2, and B3)

* two clutches (C1 and C2)

The PGM has a total of $n = 10$ links, $j = 16$ joints ($j_R = 10$ revolute and $j_G = 6$ gear joints), and 7 fundamental circuits as shown in the graph of Figure 32b. Considering $\lambda = 3$, the mobility of this PGM is calculated as follows (Eq. (24)):

$$M = 3(10 - 16 - 1) + 10 \cdot 1 + 6 \cdot 2 = 1 \text{ DOF.} \tag{24}$$

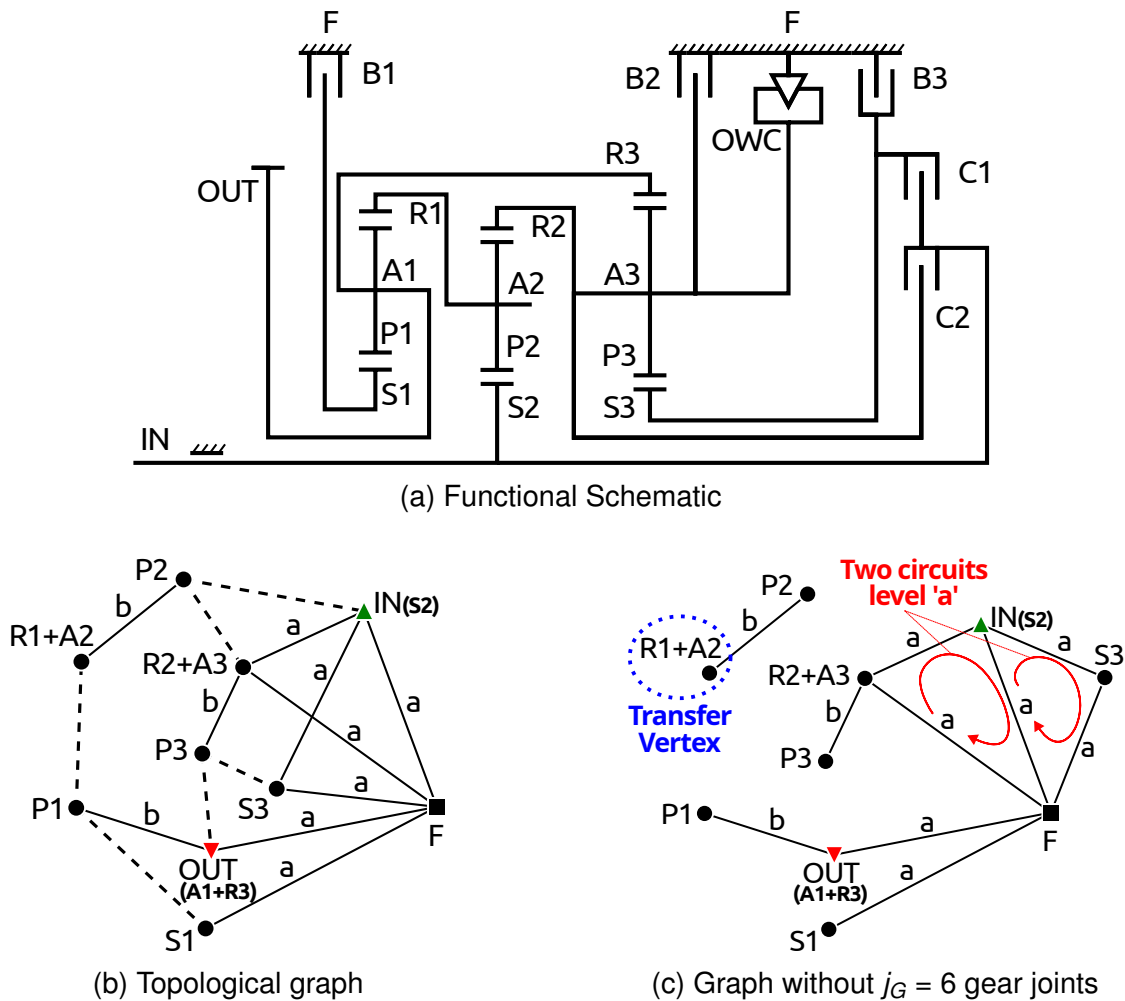

Figure 32 – Case 4: GM 6-speed model 6T40

The obtained result of 1 DOF is incorrect, as the expected mobility should be 3 DOF, comprising 1 DOF for the input rotation, and the remaining 2 DOFs for the actuation of 2 shift couplings to create power flow between the input and output links. Further analysis of the structural characteristics of the 6T40 mechanism reveals that three fundamental circuits violate structural characteristics. By removing all gear pairs from the graph (Fig. 32b), it results in a disconnected graph with two components as shown in Figure 32c.

The bigger component has two remaining circuits formed only by revolute joints at level 'a' as follows: B2:F-R2, C1:R2-IN, a:IN-F, and B3:F-S3, C1:S3-IN, a:IN-F. These are redundant circuits and must be included in the mobility calculation.

The smaller component comprises the planet (P2) connected to its corresponding arm formed by the link (R1;A2) through a revolute joint at level 'b'. According to PGT structural characteristics (BUCHSBAUM; FREUDENSTEIN, 1970), this subgraph should have the link (R1;A2) connected to a link at level 'a' through a revolute joint to function as a transfer vertex (Fig. 32c). However, the real mechanism is manufactured and operates without this joint in its topology. This phenomenon is attributed to the presence of multiple planets that are equidistantly distributed around the sun and the ring, not being assigned in the graph model. This arrangement of planets results in a combination of constraints that statically balance the arm (R1;A2) and ensure its rotation around the central axis, eliminating the need for a physical revolute joint at level 'a'. This virtual constraint should be considered in the mobility calculation.

3.1.2 Definition of Redundant Joints j_Q and Virtual Joints j_V in PGMs

As demonstrated in the case studies (Section 3.1.1), topological complexities as redundant and virtual constraints should be accounted for in the mobility equation of PGMs.

Definition 3.1.1 (Redundant Joints (j_Q)). In PGM analysis, redundant joints refer to revolute joints introduced in parallel to shift couplings between coaxial links that lack a pre-existing revolute joint. These joints represent hypothetical excess of constraints within the kinematic structure, often leading to overconstrained circuits composed solely of revolute joints at level 'a'. While feasible due to potential coaxial link arrangements, redundant joints complicate the analysis of a mechanism's motion (kinematics) and its degrees of freedom (mobility).

Redundant joints typically appear in the graph model when a shift coupling is added between coaxial links already constrained by revolute joints with other links. This connection necessitates the representation of the shift coupling but also implies the presence of an additional revolute joint. Although this configuration is physically possible (e.g., a shaft with multiple bearings), it impacts PGM mobility calculations. To ensure consistency, one revolute joint must be excluded from each redundant circuit during mobility analysis. This excluded joint is termed a "redundant joint j_{Q_i} ".

Each redundant joint corresponds to an active revolute joint at level 'a', representing $c_{R,\lambda}$ redundant constraints to the mechanism. Since redundant joints are initially included in the revolute joint count j_R in the graph representation, they must be subtracted to accurately assess the mechanism's mobility. Therefore, the accurate total joint count (j) is given by (Eq. (25)):

$$j = j_R - j_Q + j_G \quad , \quad (25)$$

where j_Q is the sum of all j_{Q_i} redundant joints in the graph.

Definition 3.1.2 (Virtual Joints (j_V)). In PGM analysis, virtual joints represent passive revolute joints at level 'a' that implicitly arise from specific arrangements of planets, sun gear, and ring gear.

Their presence is implied by the symmetrical distribution of planets, which creates a balanced set of constraints that enforce rotation of the arm around the central axis. This configuration eliminates the need for a physical revolute joint at level 'a'. While not explicitly modeled in the graph, each virtual joint (j_{V_i}) represents $c_{R,\lambda}$ constraints on the mechanism, necessitating their inclusion in mobility calculations.

Therefore, to accurately assess PGT mobility, the total joint count (j) within the mobility equation must be modified as follows (Eq. (26)):

$$j = j_R + j_V + j_G \quad , \quad (26)$$

where j_V is the sum of all j_{V_i} virtual joints in the PGM.

Considering both effects (Equations (25) and (26)), the total number of joints j must be revised as follows (Eq. (27)):

$$j = j_R - j_Q + j_V + j_G \quad (27)$$

where j_Q is the sum of each redundant joint j_{Q_i} and j_V is the sum of each virtual joint j_{V_i} .

3.1.3 A Revised Mobility Equation for PGMs

A revised mobility equation for PGMs, accounting for the effects of redundant and virtual constraints, can be obtained by substituting the total number of joints (Eq. (27)) in the general mobility equation (Eq. (9)). This results in the following expression (Eq. (28)):

$$M = \lambda(n-1) - \underbrace{(j_R + j_V - j_Q)}_{\text{revolute joints}} \cdot c_{R,\lambda} - \underbrace{j_G}_{\text{gear joints}} \cdot c_{G,\lambda} \quad . \quad (28)$$

Table 4 indicates that the degree of constraint for revolute joints is $c_{R,\lambda} = \lambda - 1$. For gear joints, the degree of constraint is $c_{G,\lambda} = 1$ with the exception to spur gear pairs in cases where $\lambda > 3$. By substituting these constraints in Equation (28), the revised mobility equation for PGMs for motion spaces up to $\lambda \leq 3$ is presented in a simple and concise form (Eq. (29)):

$$M = \lambda(n-1) - (j_R + j_V - j_Q) \cdot (\lambda - 1) - j_G \quad . \quad (29)$$

The Equation (29) is a general equation able to analyze the mobility of PGMs as only a function of the motion space and the number of joints of each type in the mechanism. When there are no redundant or virtual joints, i.e., $j_Q = j_V = 0$, the mobility equation becomes the original Grüebler-Kutzbach criterion (Eq. (10)).

3.1.4 Mobility Review of the Case Studies

Next, the revised mobility equation (Eq. (29)) is applied to each case study (Section 3.1.1) to demonstrate its validity.

3.1.4.1 Case 1: $j_Q = j_V = 0$

In Case 1 (Section 3.1.1.1), there are no redundant or virtual joints, and the mobility equation (Eq. (29)) reverts to the original Equation (10).

3.1.4.2 Case 2: $j_Q = 1$

In Case 2 (Section 3.1.1.2), the addition of clutch (C1) between arm (A) and ring (R) resulted in one redundant circuit (B1:F-A, C1:A-R, B2:R-F), which is represented by $j_Q = 1$ redundant joint. There are no virtual joints ($j_V = 0$) in this case. Substituting these joints into Equation (29) result in (Eq. (30)):

$$M = 3(5 - 1) - (5 + 0 - 1) \cdot (3 - 1) - 2 = 2 \text{ DOF.} \quad (30)$$

The obtained result aligns with the expected mobility of 2 DOF for this PGM, as discussed in the previous Section 3.1.1.2.

3.1.4.3 Case 3: $j_Q = 2$

In Case 3 (Section 3.1.1.3), the inclusion of the output link (OUT) with clutches C1 and C2 resulted in two redundant circuits (B1:F-A, C1:A-OUT, a:OUT-F and B2:F-R, C2:R-OUT, a:OUT-F), which are represented by $j_Q = 2$ redundant joints. There are no virtual joints ($j_V = 0$) in this case. Substituting these joints into Equation (29) result in (Eq. (31)):

$$M = 3(6 - 1) - (7 + 0 - 2) \cdot (3 - 1) - 2 = 3 \text{ DOF.} \quad (31)$$

The obtained result aligns with the expected mobility of 3 DOF for this PGM, as discussed in the previous Section 3.1.1.3.

3.1.4.4 Case 4: $j_Q = 2$ and $j_V = 1$

In Case 4 (Section 3.1.1.4), the PGM contains three circuits that violates the structural characteristics stated for PGTs. The first two are redundant circuits formed only by revolute joints at level 'a' (B2:F-R2, C1:R2-IN, a:IN-F, and B3:F-S3, C1:S3-IN, a:IN-F) which are represented by $j_Q = 2$ redundant joints. The third circuit (g:R2-P2, b:P2-R1, g:R1-P1, b:P1-OUT, g:OUT-P3, b:P3-R2) does not form a transfer vertex in the arm integrating the link (R1;A2). However, the presence of multiple equidistantly distributed planets (P2) around the sun (S2) and the ring (R2) statically balances the link (R1;A2), eliminating the need for a physical revolute joint at level 'a'. Although not

explicitly represented in the graph model, the virtual constraint must be accounted for by considering $j_V = 1$ virtual joint. Substituting these joints into Equation (29) yields (Eq. (32)):

$$M = 3(10 - 1) - (10 + 1 - 2) \cdot (3 - 1) - 6 = 3 \text{ DOF.} \quad (32)$$

The obtained result aligns with the expected mobility of 3 DOF for this PGM, as discussed in the previous Section 3.1.1.4.

Another evaluation of the revised mobility equation (Eq. (29)) is to consider different motion spaces as $\lambda = 2$ and 6. Applying the revised mobility equation in the motion space $\lambda = 2$ to this Case 4 results in (Eq. (33)):

$$M = 2(10 - 1) - (10 + 1 - 2) \cdot (2 - 1) - 6 = 3 \text{ DOF.} \quad (33)$$

And going to the spatial motion space $\lambda = 6$ to this Case 4 results in (Eq. (34)):

$$M = 6(10 - 1) - (10 + 1 - 2) \cdot (6 - 1) - 6 = 3 \text{ DOF.} \quad (34)$$

Both obtained results align with the expected mobility of 3 DOF for this PGM, showing the applicability of the revised mobility equation (Eq. (29)) in different motion spaces.

3.1.5 Mobility Discussions and Contributions for PGMs

The analysis of mobility in PGMs has led to important discussions and contributions. One significant aspect is the consideration of redundant and virtual joints within the mobility equation.

Redundant joints offer the potential to expand the number of gear ratios in PGMs by introducing additional shift couplings. However, it is essential to exclude the redundant constraints from the mobility calculation.

On the other hand, virtual joints arise due to combined constraints resulting from the equidistant distribution of multiple planets, ensuring rotational degrees of freedom relative to the central axis of certain links, such as the arm and the ring. These constraints cannot be directly identified in the graph representation of PGMs, as they depend on the complete graph (not simplified) and the geometric position of components not assigned in topological graph representation. Thus, it is necessary to include these combined constraints in the mobility equation.

The identification of redundant and virtual joints in PGMs can be achieved by removing all gear joints from the graph and applying search algorithms (SKIENA, 2008), such as Depth-First Search (DFS) or Breadth-First Search (BFS), to detect remaining circuits (indicating redundant joints) and disconnections (indicating virtual joints).

3.2 PGM: COMPLEXITY AND CAPABILITY

In the preceding sections, the complex topology of PGMs has been highlighted, illustrating the myriad of combination possibilities available to meet functional requirements.

As this metrics section begins, it is crucial to emphasize a few points. While there is an abundance of methods for the enumeration and synthesis of kinematic chains, these methods produce a considerable volume of chains. However, bridging the gap between theoretical outcomes and their practical applications poses challenges. Predominantly in industrial practice, solutions are frequently driven by economic factors and the pursuit of manufacturing efficiency, with a common objective of simplifying assembly processes. This inclination towards simplicity often leads to a reduction in overall complexity. Such simplified solutions demand thorough evaluation, emphasizing the need for a well-defined complexity criterion. Rare works like [Karhula and Nicolai \(2018\)](#) and [Köller and Schmitz \(2022\)](#) do utilize certain complexity metrics; however, these metrics do not adequately capture the topological complexity inherent to the PGMs.

Within this section, the objective is to present and refine a more suitable complexity criterion. Once articulated, this metric will be subsequently employed for the analysis or optimization of planetary gear trains.

[Suh \(2005\)](#) refers to complexity, in this context, as the uncertainty in satisfying functional requirements within the design range. The author highlights the importance of measuring topological complexity in engineered systems to improve design and operation efficiency and move away from trial-and-error approaches. According to [Hennig et al. \(2022\)](#), understanding the complexity of systems is considered a primary driver of adverse project outcomes, including cost, schedule, and scope overruns. They conducted a rigorous benchmarking study on complexity measures for engineering systems and found numerous studies but little consensus on "how" complexity should be measured and what constitutes a good measure. However, the literature consistently expects that complexity growth is correlated with increases in size, the number of interconnections, and the randomness of the system architecture. As stated by [Sinha and Suh \(2018\)](#), structural complexity arises when a system has many components, and the interaction between them is difficult to describe or understand. [Elmaraghy et al. \(2012\)](#) reviewed in deep the complexity metrics for design process, products, manufacturing, and business. For them, the increase in complexity should be justified only if it improves system capabilities and performance, but should otherwise be minimized. Regardless of the objective, it is important to characterize and measure complexity at all levels.

It becomes evident that measurement of the topological complexity of PGMs can assist in the decision-making process for design, enabling the determination of more suitable design requirements, including parameters and values. Mechanisms with

higher functional capacity and lower topological complexity are considered more topologically efficient, potentially impacting costs, production, operation, and maintenance. Moreover, in cases of isomorphisms and pseudoisomorphisms, complexity serves as a decisive metric in differentiating between them.

Although the term *complexity* is widely used in discussions about PGM topology, but there is limited literature on measuring the complexity itself of these mechanisms. [Freudenstein and Maki \(1979\)](#) attribute the complexity to the number of independent circuits or closed loops in the mechanism. [Tsai \(2001\)](#) suggests parameters that may increase mechanism topology complexity, such as the number of loops, vertices, length of peripheral loops, use of clutches for connecting PGSs, and presence of floating carriers, but does not utilize them for this purpose. Similarly, [Karhula and Nicolai \(2018\)](#) and [Karhula et al. \(2019\)](#) emphasize that the complexity of automatic transmissions can be assessed by the sum of shift couplings and gear pairs, wherein the design process aims to optimize capability while minimizing complexity. In a recent work, [Köller and Schmitz \(2022\)](#) restricted the complexity of PGMs to the cumulative count of major components, including gears, synchronizers, clutches, and brakes.

The aforementioned parameters are important for analyzing PGM complexity; however, they are limited to individual entities or subchains of the mechanism. Solely, they fall short in capturing the overall complexity of the mechanisms. A more in-depth metric for complexity can improve the comparative assessment of mechanisms and support the selection of optimal parameters during the design phase. In the subsequent sections, improved metrics to quantify complexity and capability inherent to PGMs will be presented.

3.2.1 PGM Structural Complexity Metric

The PGM structural complexity metric applied in this thesis is an adaptation of the work of [Sinha and Weck \(2013\)](#), which presents an interesting approach to measuring structural complexity for engineered complex systems. This approach provides a comprehensive characterization by capturing complexities of individual components (local effect), pairwise interfaces (local effect), and the system's architecture (global effect). An overview of the structural complexity metric is shown in [Figure 33](#).

In this thesis, the structural complexity metric ([Fig. 33](#)) is adapted to fit the domain of PGMs. In order to avoid misinterpretation on symbols of variables, the structural complexity metric will be designated by C_x , and thus also extended to its components as shown below ([Eq. \(35\)](#)).

$$C_x(n, j, A) = \underbrace{C_{x_1}}_{\text{links}} + \underbrace{C_{x_2}}_{\text{joints}} \cdot \underbrace{C_{x_3}}_{\text{topology}}, \quad (35)$$

where n is the number of links, j is the number of joints and A is the adjacency matrix.

Figure 33 – Overview of the structural complexity metric.

Source: Adapted from Sinha and Suh (2018).

3.2.1.1 PGM Link Complexity (C_{X_1})

Link complexity (C_{X_1}) represents the combined complexity of all links in a mechanism and is calculated by summing (Eq. (36)) their individual complexities (α_i):

$$C_{X_1} = \sum_{i=1}^N \alpha_i \quad (36)$$

Individual complexities (α_i) focus on the technical design difficulty of each component, without considering complexity stemming from interfaces (SINHA, 2014). Factors such as performance, size, reliability, knowledge requirements, and reusability should inform this assessment. Estimation methods may include expert opinion (when reliable data are unavailable), technological maturity (Technology Readiness Level - TRL), or data analytics.

An improved mathematical formulation is presented in this thesis to represent individual complexity (α_i) of a PGM link i , described as (Eq. (37)):

$$\alpha_i = k(i) + \left(CL_{factor}(links_i) \cdot \sum_{l=1}^{l_i} \alpha_{link,l} \right), \quad (37)$$

where:

- $k(i)$ is the degree of adjacency (e.g., binary, ternary).
- $links_i$ is the sequence of elementary links composing link i .
- $CL_{factor}(links_i)$ is a weighting factor for compound links (CL), accounting for radial transition costs between elementary links.

- $\alpha_{link,l}$ is the relative individual complexity of each elementary link within link i , as presented in Table 11.

For compound links, the CL_{factor} weights the complexity based on radial level transitions between elementary links. It is calculated as the product of individual transition costs (Eq. (38)). Transitions among sun gear (S), arm (A), and ring gear (R) incur complexity penalties as outlined in Table 10. Higher values indicate more complex radial transitions within the compound link. For single links, the CL_{factor} is 1.

$$CL_{factor} = \prod_{i=1}^{n-1} C(link_i, link_{i+1}) \quad , \quad (38)$$

where $C(link_i, link_{i+1})$ is the transition cost between two consecutive elementary links.

Table 10: Compound link transition cost conditions.

Condition	Transition	$C(link_i, link_{i+1})^*$
C1	Same link level (ex. S1;S2, A1;A2, R1;R2.)	1.03
C2	Between arm (A) level to other levels (ex. A1;S2, A1;R2)	1.05
C3	Between sun (S) and ring (R) levels (ex. S1;R2, R1;S2)	1.07

* Cost of each individual transition.

Source: Author.

Relative complexity values are assigned based on the author's expertise, comparing all elementary links within a PGS and treating the input shaft (singly) as the simplest component. Factors considered include geometry, design uniqueness, manufacturing processes, modularity, tolerances, and material requirements. Individual complexity (α_j) of a compound link is the sum of the complexities of its constituent elementary links multiplied by their transition factors.

Table 11 – Relative individual complexity attributed to elementary links of PGMs.

Link	Symbol	α_{link}
Input shaft	IN	1.0
Output shaft	OUT	1.0
Sun	S	1.5
Planet	P, PS, PR	1.6
Arm	A	1.8
Ring	R	1.9
Frame	F	5.0
Others		1.0

Source: Author.

As an illustrative example, consider a quinary ($k(i) = 5$) compound link consisting of the following elementary links sequence: A1 → R2 → S3 → S4. The compound link factor (CL_{factor}) is calculated as follows:

- A1 → R2: (C2) Transition between arm level and other level → $C(A1, R2) = 1.05$
- R2 → S3: (C3) Transition between sun and ring levels → $C(R2, S3) = 1.07$
- S3 → S4: (C1) Same link level → $C(S3, S4) = 1.03$

Therefore:

$$\begin{aligned} CL_{factor} &= C(A1, R2) \cdot C(R2, S3) \cdot C(S3, S4) \\ &= 1.05 \cdot 1.07 \cdot 1.03 \\ &\approx 1.157 \end{aligned}$$

The relative individual complexity $\alpha_{link,l}$ is calculated as follows:

- A1: Arm → $\alpha_{link}(A1) = 1.8$
- R2: Ring → $\alpha_{link}(R2) = 1.9$
- S3: Sun → $\alpha_{link}(S3) = 1.5$
- S4: Sun → $\alpha_{link}(S4) = 1.5$

Therefore:

$$\begin{aligned} \sum_{l=1}^4 \alpha_{link,l} &= \alpha_{link}(A1) + \alpha_{link}(R2) + \alpha_{link}(S3) + \alpha_{link}(S4) \\ &= 1.8 + 1.9 + 1.5 + 1.5 \\ &= 6.7 \end{aligned}$$

And finally, the individual complexity (α_j) of this compound link result as:

$$\alpha_j = 5 + (1.157 \cdot 6.7) \approx 12.753 \quad .$$

It is important to note that this assessment is qualitative and serves as a starting point for individual complexity analysis.

3.2.1.2 PGM Coupling Complexity (Cx_2)

The coupling complexity (Cx_2) in the mechanism represents the complexities arising from their couplings, encompassing joints (kinematic pairs) and actuators (active couplings). It is calculated by summing the pairwise complexities ($\beta_{i,j}$) of each coupling (Eq. (39)):

$$Cx_2 = \sum_{i=1}^n \sum_{j=1}^n \beta_{i,j} \cdot A_{i,j} \quad , \quad (39)$$

where $A_{i,j}$ is the adjacency matrix related to the PGM graph.

As suggested by Sinha (2014), the pairwise complexity ($\beta_{i,j}$) of each coupling interface (i and j) can be estimated based on a function that considers the complexities of the interfacing components (α_i, α_j) and the characteristic properties of the interface

type. In this thesis, for simplicity, the pairwise complexity of each coupling in a PGM is given by (Eq. (40)):

$$\beta_{i,j} = \beta_{kp} \cdot \max(\alpha_i, \alpha_j) \quad . \quad (40)$$

Where $\max(\alpha_i, \alpha_j)$ captures the higher link complexity in the pair and β_{kp} is the relative pairwise complexity attributed to couplings based on the pair characteristics such as type, level, and function, according to the author's expertise as detailed in Table 12.

Table 12 – Relative pairwise complexities attributed to couplings of PGMs.

Coupling Type	Level	β_{kp}
Virtual	<i>a</i>	0.0
Revolute (planets)	<i>b</i> or higher	1.0
Revolute (coaxial)	<i>a</i>	1.2
Input	<i>a</i>	1.3
Output	<i>a</i>	1.3
External Gear	<i>g</i>	1.4
Internal Gear	<i>g</i>	1.5
Brake	<i>a</i>	1.8
Clutch	<i>a</i>	2.0

Source: Author.

The planets revolute joints (level 'b' or higher) were considered the simplest joint in PGMs and has been designated a reference complexity value of 1.0. The coaxial revolute joints (level 'a'), which require critical alignment, lubrication channels, and the inclusion of additional components such as bearings, have been rated at 1.2 in complexity. Owing to their sealing prerequisites, input/output shaft joints have been assigned a relative complexity of 1.3. In addition to geometric complexity, gear meshes require precise tolerances to maintain center distances. Sun-planet external gearing has been attributed a complexity of 1.4, while planet-ring internal gearing has been assigned a value of 1.5. Shift couplings, typically multifaceted in design and demanding precision in hydraulic operation, are regarded as having the highest complexity among joints. Brakes, which are anchored to the housing, were given a complexity rating of 1.8. Furthermore, clutches between two movable links have been determined to have a complexity of 2.0, primarily attributed to the increased challenges associated with accessing the hydraulic fluid essential for their operation.

It is imperative to acknowledge that these values serve as an initial reference, and real-world complexities might be detailed depending on specific design requirements and operational scenarios. A more rigorous complexity index for lower kinematic pairs, grounded in the concept of *loss-of-regularity*, is introduced by Khan et al. (2007). However, no literature addresses the complexity of higher kinematic pairs, especially gear pairs in PGM transmissions.

3.2.1.3 PGM Topological Complexity (Cx_3)

The topological complexity metric (Cx_3) originates from interaction between elements and depends on the nature of such connectivity structure, being determined as (Eq. (41)):

$$Cx_3 = \frac{1}{n} \cdot E(A) \quad , \quad (41)$$

where

$$E(A) = \sum_{i=1}^n \sigma_i \quad . \quad (42)$$

$E(A)$ is the graph energy resulted as the sum of the singular values (σ_i) obtained by the singular value decomposition of the adjacency matrix A .

As depicted by [Sinha \(2014\)](#), the Cx_3 is associated with the topology pattern of the graphs as follows:

$Cx_3 < 1$: *hypoenergetic* \Rightarrow Centralized Architecture

$1 \leq Cx_3 < 2$: *transitional* \Rightarrow Hierarchical/Layered Architecture

$Cx_3 \geq 2$: *hyperenergetic* \Rightarrow Distributed Architecture

The structural complexity metric can provide a comprehensive assessment of mechanisms, considering both individual and collective complexities. It is important to note that the specific formulation and calculation methods for these features must be adapted depending on the mechanisms and specific requirements of each study.

3.2.2 PGM Capability Metric

Capability metrics are designed to quantify the ability of mechanisms to perform their designated tasks and to evaluate their performance. Such metrics are commonly associated with the functional requirements of mechanisms and are sometimes referred to as performance metrics. Parameters related to the kinematics, statics, and dynamics of mechanisms in both local and global configurations are evaluated by these metrics ([RUSSO, 2022](#)).

In this thesis, a mechanism functional capability metric (Ca) is introduced. This metric intends to capture a functional trade-off between benefit and cost: a quantifiable output related to the primary function of the mechanism and its actuation efficiency. It is defined as follows (Eq. (43)):

$$Ca = Ca_1 + Ca_2 \quad , \quad (43)$$

where Ca_1 is the term associated with a quantifiable output performance metric, and Ca_2 is the term associated with actuation efficiency.

3.2.2.1 PGM Performance metric (Ca_1)

The choice of a performance metric (Ca_1) is influenced by the type of mechanism and the specific function under consideration. It might be the global conditioning index for robots, the maximum displacement for a linkage, or other relevant metrics.

For PGMs, the output performance metric is determined by their number of forward gears, as given by (Eq. (44)):

$$Ca_1 = \text{Gears}_{FWD} \quad (44)$$

3.2.2.2 PGM Actuation Efficiency metric (Ca_2)

The actuation efficiency metric (Ca_2) is defined as the reciprocal of the mechanism's mobility:

$$Ca_2 = \frac{1}{M} \quad , \quad (45)$$

where M denotes the mobility.

Thus, when mechanisms are compared, a higher output response combined with a reduced required actuation for its achievement indicates a superior mechanism functional capability metric Ca .

Such a capability metric offers a quantitative assessment of mechanisms' abilities and facilitates a thorough analysis of their functionality.

3.3 CHAPTER HIGHLIGHTS

In Chapter 3, a thorough review of the PGM graph model was conducted. An assumption was made wherein all shift couplings possess a parallel revolute joint to be depicted accurately in the topological graph. This assumption can yield overconstraints, resulting in redundant circuits of revolute joints at level 'a'. Additionally, virtual constraints were recognized, emerging from the assembly of equidistantly distributed planets around the sun and ring. A revised mobility equation, referenced as (Eq. (29)), has been introduced in this thesis. This revised equation enhances the Grübler-Kutzbach criterion (Eq. (10)), providing a comprehensive analysis of the mobility of complex PGMs by incorporating considerations for redundant and virtual constraints. The equation's accuracy was validated through four case studies, demonstrating its effectiveness in predicting the correct mobility of PGMs in any motion space. This contribution enhances the understanding of PGM kinematic structures as a whole and supports advancements in PGM design and innovation.

Moreover, novel metrics designed for evaluating the performance of mechanisms, premised on their topological characteristics, were introduced in this chapter. These metrics, conceived to analyze complexity and capability of various mechanisms, are

discussed with particular emphasis on their application to PGMs. An in-depth application and discussion on the structural complexity and capability metrics for PGMs is presented in Chapter 5, wherein the technological performance indexes for innovation are characterized.

4 PROCESS FOR DISCOVERING INNOVATIVE GAPS IN MECHANISMS DATABASE

This chapter provides an overview of the process proposed for this thesis research. As mentioned in [Chapter 1](#), the design process of automotive planetary transmissions can benefit from a systematic approach for innovation to assist engineers in identifying relevant structural parameters and characteristics to design new mechanisms. To address these challenges, the research question posed is: *"Is it possible to discover potential innovative gaps in the requirements for designing automotive planetary gear trains by analyzing an extensive and diverse database?"* The primary objective of this thesis is **to introduce a new process for identifying potential innovative gaps in the requirements for designing new automotive planetary gear mechanisms through comprehensive database analysis.**

The proposed process is divided into four key phases:

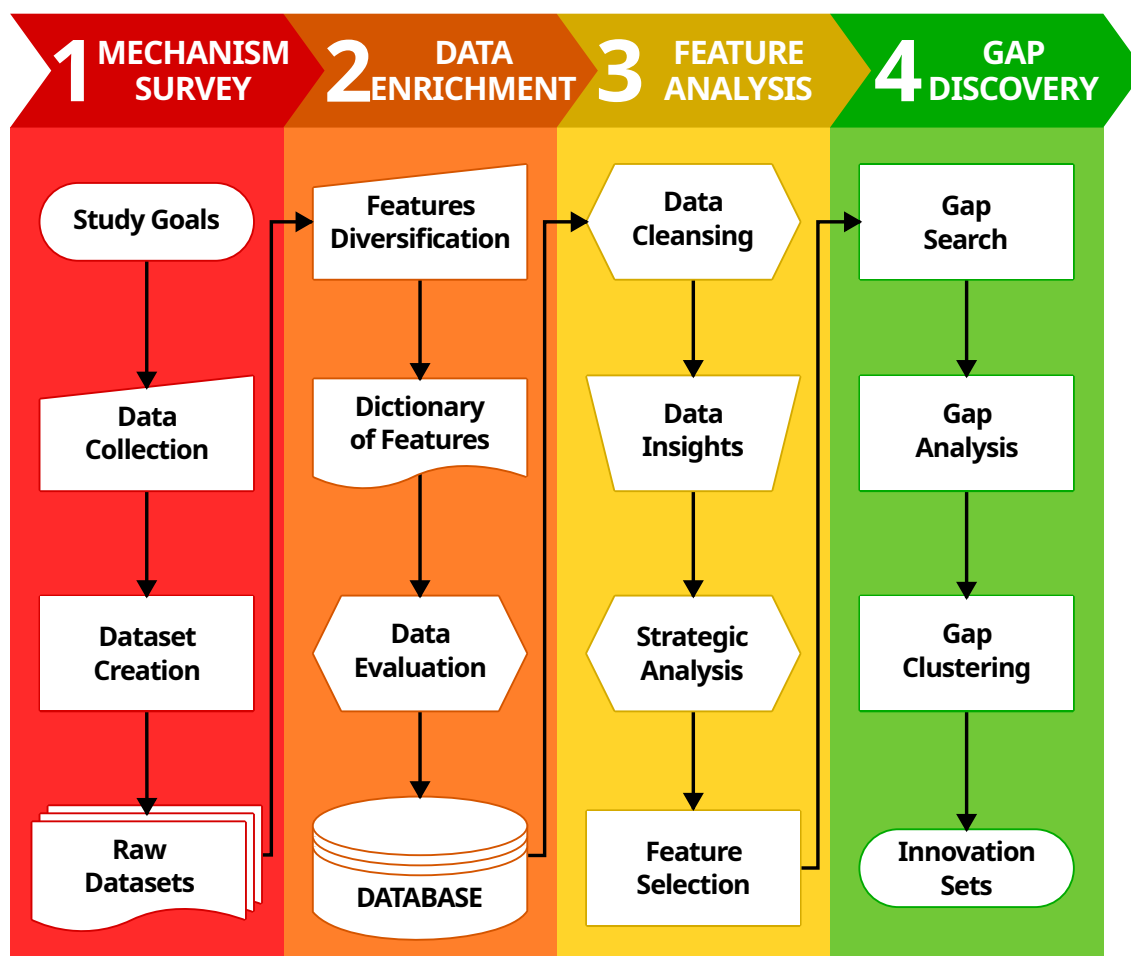

1. **MECHANISM SURVEY:** Conduct a comprehensive study and review of existing Planetary Gear Mechanisms (PGMs) by gathering relevant data and information from patent, academic, and industry sources. This phase involves generating extensive datasets.
2. **DATA ENRICHMENT:** Create a diverse dictionary of features related to automotive Automatic Transmissions (AT) based on planetary gear trains. Evaluate the datasets and generate a structured comprehensive database.
3. **FEATURE ANALYSIS:** Use data science strategies to analyze the characteristics of features involved in the design of automotive planetary gear trains. Select the most relevant features as a result of this analysis.
4. **GAP DISCOVERY:** Assess the boundaries of the selected features and discover gaps in data. Combine the relevant feature gaps and select the most promising ones as potential innovation sets for input in the design of new automotive transmissions.

In [Figure 34](#), a diagram illustrating the proposed workflow of the process for discovering potential innovative gaps in automotive planetary gear trains database is presented, containing each phase and their associated methods.

As depicted in [Figure 34](#), the process is versatile and is not exclusively limited to PGMs, it can be applied to projects involving various types of mechanisms. This chapter introduces the process tailored for the discovery of potential innovative gaps in generic mechanisms. The subsequent [Chapter 5](#) delves into its application specifically to the case study of PGTs.

To provide a thorough understanding of the process, a brief review on the knowledge discovery in databases is presented in [Section 4.1](#). Subsequently, each phase is described in detail in the following [Sections 4.2 to 4.5](#), highlighting the significance

Figure 34 – Process for Discovering Potential Innovative Gaps.

Source: Author.

of the methods employed, their relevance in the research context, and any limitations associated with their implementation.

4.1 REVIEW OF KNOWLEDGE DISCOVERY IN DATABASES (KDD)

According to [Witten et al. \(2017\)](#), *information* is the set of patterns or expectations existing in recorded facts in its raw form, known as *data*. There is a huge amount of information locked up in databases-information that is potentially important but has not yet been discovered or articulated.

The *Knowledge Discovery in Databases (KDD)* is defined by [Fayyad \(1996\)](#) as:

... the nontrivial *process* of identifying *valid, novel, potentially useful, and ultimately understandable patterns* in *data*.

Data is typically obtained through observations or measurements, which can be unprocessed or processed. It is described by *features* (also known as attributes, properties, characteristics, parameters, or variables) associated with *values* represented as text, numbers, or multimedia. The data associated with a unique body of work is

referred to as an *instance*, and these instances are stored in a structured collection named a *dataset*. Multiple datasets form a *database*, which is an organized collection of data that can be electronically accessed, manipulated, and updated.

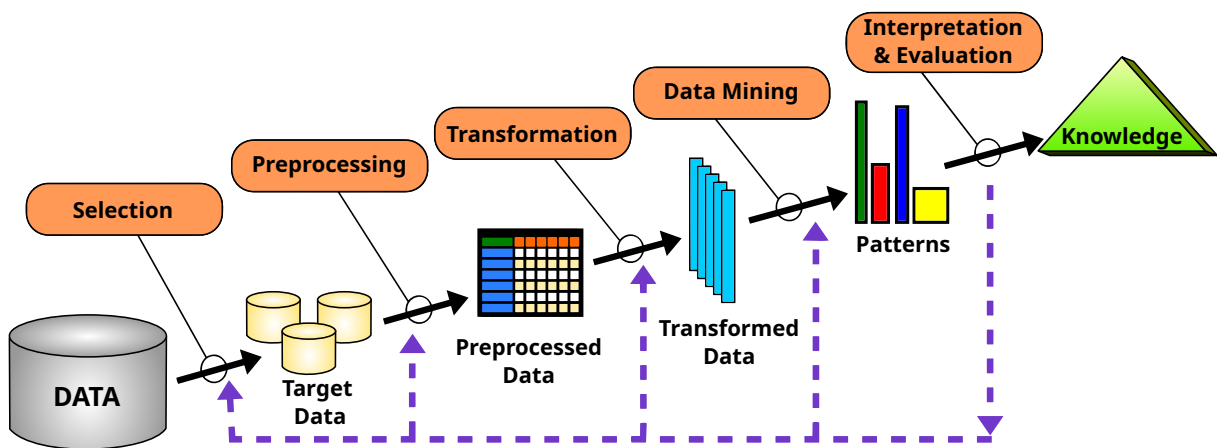

The *dimensionality of the data* is determined by the number of features it contains, while *patterns* represent abstract representations of subsets of the data. Instances within a dataset can be categorized into *classes* based on specific aspects.

Formally, a dataset can be simply represented as $\mathbf{X} = \{x_1, \dots, x_d\} \in \mathbb{R}$. The class label is represented as $\mathbf{Y} = \{y_1, \dots, y_N\}$. A typical dataset is organized as a matrix of N rows (instances) by d columns (features) and an extra column with the class labels (Eq. (46)):

$$\mathbf{X}_{N \times d} = \left. \begin{array}{cccc} & \text{features} & & \\ & \overbrace{\quad\quad\quad} & & \\ x_{11} & x_{12} & \cdots & x_{1d} \\ x_{21} & x_{22} & \cdots & x_{2d} \\ \vdots & \vdots & \ddots & \vdots \\ x_{N1} & x_{N2} & \cdots & x_{Nd} \end{array} \right\} \text{instances}, \quad \mathbf{Y}_{N \times 1} = \left. \begin{array}{c} \text{class} \\ y_1 \\ y_2 \\ \vdots \\ y_N \end{array} \right\} \quad (46)$$

The primary objective of the KDD process is to extract knowledge by exploring databases through a series of iterative steps, including data preparation, selection, pre-processing, transformation, data mining, and evaluation. The KDD process is illustrated in Figure 35. It is important to note that the term Data Mining (DM) is often used inter-

Figure 35 – Overview of the KDD process.

Source: Adapted from Fayyad (1996).

changeably with KDD, but it specifically refers to the step within the KDD process where specific algorithms are applied to extract patterns from the data (HAN et al., 2012). Data mining focuses on the computational techniques used to uncover meaningful patterns, relationships, and trends in the data. From understanding the problem to its completion with useful knowledge, the KDD process can be briefly described in the following steps:

1. **PROBLEM DEFINITION:** Define the application domain, incorporate relevant prior knowledge, and identify the KDD's goal to establish the context and objectives of the data analysis.
2. **SELECTION:** Gather and select the necessary data from multiple sources to create a dataset that accurately represents the problem domain.
3. **PREPROCESSING:** Remove noise and outliers, handle missing data fields, account for time-sequence information and known changes, and apply appropriate normalization techniques to enhance data quality and consistency.
4. **TRANSFORMATION:** Extract relevant attributes, perform dimensionality reduction, and transform the data to ensure its suitability for data mining algorithms and techniques.
5. **DATA MINING:** Search for patterns of interest and usefulness within the dataset using selected algorithms and models suitable for the KDD's goal.
6. **INTERPRETATION & EVALUATION:** Validate and explain the results of the data mining process for reliability and significance, and utilize visualization techniques to present the findings in a comprehensible manner.
7. **KNOWLEDGE:** Present the mined knowledge to users and integrated into existing systems or applications to enhance their functionality.

KDD is an interdisciplinary field that encompasses various disciplines such as statistics, machine learning, artificial intelligence, reasoning with uncertainty, databases, knowledge acquisition, pattern recognition, information retrieval, visualization, intelligent agents, digital libraries, and management information systems (FAYYAD, 1996).

As mentioned earlier in this chapter, the focus of this thesis is to determine relevant features (characteristics) for identifying gaps (values not covered in patterns) in a mechanism database. The ultimate goal is to generate potentially innovative sets of requirements for designing new mechanisms. In the following sections, each phase of the proposed process (as shown in [Figure 34](#)) is described.

4.2 PHASE 1: MECHANISM SURVEY

The *Mechanism Survey* phase is characterized by the establishment of study objectives and the collection of essential information required for the generation of datasets related to the mechanisms under study. This phase encompasses the subsequent steps:

1. **STUDY GOALS:** Review of the research scope, specifying the mechanism type, and articulating the objectives.
2. **DATA COLLECTION:** Retrieving initial data related to the essential design requirements of existing mechanisms from reliable sources such as patent databases,

academic articles, and reports from manufacturers.

3. **DATASET CREATION:** Creation of a dataset template for inputting and validating the collected data of each mechanism to ensure accuracy.
4. **RAW DATASETS:** Set of datasets containing all valid mechanisms collected data intended for further analysis.

The output of phase 1 is the formulation of raw datasets that encompass existing mechanisms, thereby facilitating subsequent analytical and synthesis processes.

4.2.1 Study Goals

The initial step in phase 1 involves translating customer requirements into clear, technical, and objective directives. This step aids in the identification of the mechanism type and the delineation of the study's objectives, guiding the overall process. Key information and their attributes include:

1. *Mechanism Type Identification*
2. *Goal and Objective Specification:* Definition of the overall goal and specific objectives to be accomplished through data analysis.
3. *Data Source Specification:* Identification of sources from which data will be retrieved.
4. *Scope Definition:* Determining the boundaries pertinent to the analysis.
5. *Constraint Consideration:* Identification of potential constraints or limitations that might influence the data analysis process.
6. *Evaluation Criteria Establishment:* Delineating the criteria for assessing the efficacy of the data analysis efforts.

4.2.2 Data Collection

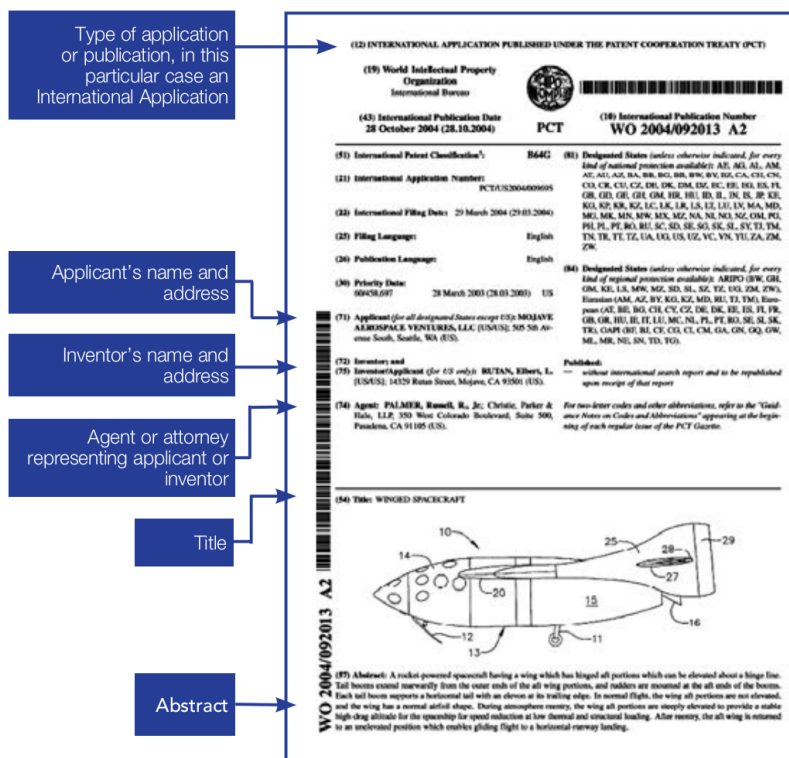

The second step of phase 1 is focused on collecting essential data related to existing mechanisms. This involves sourcing data from trustworthy repositories such as patent databases, academic publications, and manufacturers' documentation.

4.2.2.1 Patent Search

According to [WIPO \(2015\)](#), patent information is a valuable source of technological information presented in a standardized format. It is considered the world's largest repository of technological information ([ARISTODEMOU; TIETZE, 2018](#)).

A patent typically consists of various fields of information, including bibliographic data, claims, detailed description, drawings, background, abstract, and summary ([WIPO, 2011](#)). [Figure 36](#) illustrates an example of the front page of an international patent application.

Figure 36 – Front page of an international patent application.

Source: Adapted from [WIPO \(2015\)](#).

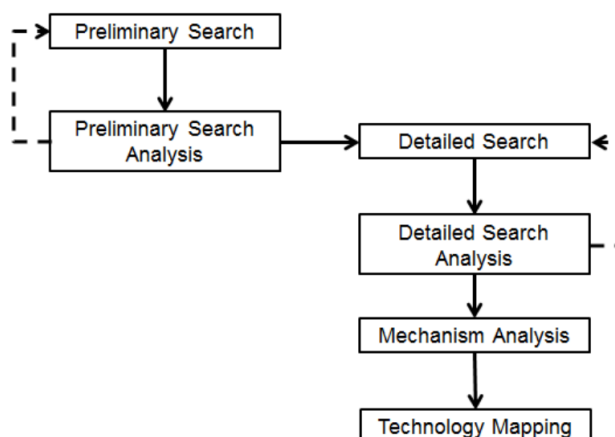

In the context of enumeration-based mechanism design, patent analysis is used to review existing designs, identify relevant information on structural and functional characteristics of mechanisms, and inspire designers to create new concepts while avoiding protected solutions. [Freudenstein and Maki \(1979\)](#) suggested cross-indexing mechanical patents with a simple structural formula to facilitate prior art searches.

LAR Patent Search Methodology Proposed by the author's research group ([HOELTGEBAUM et al., 2016b](#)), this process focuses on patent search for automotive mechanisms. The primary objective is to identify the structural characteristics, such as mobility, number of independent loops, and order of the space, of the inventions and use them as initial structural requirements for the design of new mechanisms. The process consists of six steps: preliminary search and analysis, detailed search and analysis, mechanism analysis, and technology mapping ([Fig. 37](#)). The preliminary and detailed search steps are iterative in nature.

The LAR methodology is the recommended patent search method for this step.

Patent Data Sources When conducting a patent search, it is essential to utilize reliable and comprehensive sources of patent data. There are several recognized world-wide open databases that can be utilized for this purpose. Some of the recommended sources include:

Figure 37 – LAR Patent Survey Methodology

Source: Hoeltgebaum et al. (2016b).

1. *ESPACENET*: A free online patent database provided by the European Patent Office (EPO) offering access to patent documents from around the world, including the EPO, WIPO, USPTO, and many other national patent offices.
2. *USPTO*: A comprehensive database of patents provided by the United States Patent and Trademark Office (USPTO). It is a valuable resource for accessing patent information from the United States.
3. *WIPO*: The World Intellectual Property Organization (WIPO) offers a global database named PATENTSCOPE, which provides access to both international and national patent applications from various countries and regions.
4. *INPI*: The National Institute of Industrial Property (INPI) is an important source for accessing patent information specific to Brazil.
5. *Google Patents*: An extensive online database that provides access to a wide range of patent documents from various jurisdictions around the world such as USPTO, EPO, WIPO, and many others.

4.2.2.2 Academic and Industry Search

Not all the required information is available in patents, such as the functional characteristics and physical properties of the related commercial product, e.g., weight, torque capacity, and others. Therefore, information beyond patent search can be accessed through academic and industry search.

Academic Search This step involves finding books, studies, and research papers that focus on the properties and characteristics of mechanisms. Academic databases such as IEEE Xplore, ScienceDirect, and Google Scholar can be valuable sources for accessing scientific literature. By reviewing academic publications, it is possible to

gather insights into the performance, efficiency, durability, and other important attributes of mechanisms.

Industry Search This step involves exploring suppliers' technical reports and product documentation. These sources provide detailed information about the commercial aspects of mechanisms, including specifications, performance data, operational parameters, and design considerations. Manufacturers' websites, product catalogs, and technical manuals can be used to extract essential information for mechanism analysis and comparison.

By incorporating both academic and industry search approaches to the patent search results, it is possible a comprehensive understanding of mechanisms, considering both their technical and commercial aspects. This enriched information enables a more thorough evaluation of existing mechanisms and facilitates the identification of opportunities for innovation and improvement.

4.2.3 Datasets Creation

The data collected from each mechanism in the previous step must be transformed into a suitable graph representation ([Section 2.3.1](#)), validated, and stored as datasets for subsequent analysis.

Typically, the structural characteristics are extracted from mechanism representations in figures of data sources, requiring visual analysis by the designer.

Functional characteristics vary depending on the type and purpose of the mechanism. They are often presented in tables or sentences that need to be read and interpreted before being input into the dataset.

Technical characteristics, such as dimensions, cost, weight, and others are typically retrieved from industrial and academic sources.

In order to achieve standardized, reliable, and replicable data collection with facilitated data input and automated data validation, the adoption of a dataset template is highly recommended. This template should encompass the identification of each mechanism, along with its structural, functional, and technical attributes. Moreover, to ensure data accuracy and reliability, the automated validation of the mechanism's structural characteristics within the dataset template is essential.

A proposed dataset template for mechanisms comprises the following fields:

- A. **Dataset Template:** A structured format designed for the data insertion of each mechanism, equipped with automated validation functionalities for enhanced reliability (e.g., spreadsheet templates).
- B. **Input data:** Required data to create each dataset.
 - (a) Identification: Data pertinent to the recognition of individual mechanisms.

- i. *Source*: Data origin, such as patents, academic articles, manufacturer brochures, among others.
 - ii. *Date*: Release date associated with the mechanism, predominantly available in the source.
 - iii. *Model*: Mechanism identifier or descriptor as presented in the source.
 - iv. *Others*: Any supplementary information deemed vital to the mechanism's categorization.
- (b) Structural Characterization: Data related to the topology and inherent structural attributes based on the mechanism representation.
- i. *Topology*: List of the mechanism's links and joints.
 - ii. *Actuators*: List of the mechanism's actuators.
 - iii. *Structural Validation*: Automated methods for evaluating and validating structural characteristics such as mobility, among others.
- (c) Functional Characterization: Data addressing functional requirements of the mechanisms, including performance metrics, power outputs, controls, among others.
- (d) Technical Characterization: Data related to product specifications like dimensions, cost, application, among others.

By employing this dataset creation method, data relevant to each mechanism is systematically organized, thus facilitating subsequent steps towards the identification of potential innovative gaps in the mechanism database.

4.2.4 Raw Datasets

The output of Phase 1 is a collection of raw datasets, consisting of essential and reliable data generated from the analyzed mechanisms. For effective management of this collected data, the implementation of a dataset control system is recommended. This system should encompass a comprehensive dashboard, and be supplemented with version control functionalities. Such provisions are essential to ensure the data integrity and organization throughout the research process.

4.3 PHASE 2: DATA ENRICHMENT

In the second phase, termed *Data Enrichment*, datasets are augmented with additional features to maximize the available information regarding the mechanisms. This phase encompasses the following core steps:

1. **FEATURES DIVERSIFICATION**: Identify additional features from diverse related domains for inclusion.

2. **DICTIONARY OF FEATURES:** Create a dictionary to characterize and recognize all features to be assessed within the datasets.
3. **DATA EVALUATION:** Assess all instances in the datasets with respect to the newly introduced features.
4. **DATABASE:** Store the enriched data in an organized collection, ensuring efficient retrieval and subsequent analysis.

The output of phase 2 is a comprehensive database containing enriched data aiming to enhance the understanding of the studied mechanisms. This enriched foundation opens the way for potential discovery of patterns and relationships in the following phases of the process.

4.3.1 Features Diversification

The diversification of features is essential in augmenting the utility and insights obtained from the collected data. This process includes the incorporation of additional features, which elucidate the structural, functional, and technical characteristics of the mechanisms. More precisely, it involves the identification and enhancement of measures sourced from diverse related domains for inclusion into the feature set.

Graph theory represents an essential domain in the study of mechanisms. Due to their multidisciplinary nature, numerous properties and measurements are possible for graph characterization (F. COSTA et al., 2007). Within the scope of this research, a detailed emphasis is given to the topological properties for the representation of mechanisms.

Metrics of topological nature, depending solely on the information within the adjacency matrix (Section 2.3.1), can be associated with various attributes such as distance, connectivity, clustering, centrality, and spectral measures, to name a few (HERNÁNDEZ; MIEGHEM, 2011). These metrics, either on a global scale, representing the mechanism as an entirety (graph topology), or on a local scale, illustrating the features of individual links (vertices) or joints (edges), can be found in the literature (OEHLERS; FABIAN, 2021).

In the subsequent sections, two primary approaches are proposed: local and global features.

4.3.1.1 Local features

Local features are measures related to individual components of the mechanism, namely links and joints. When the interrelations of key individual components, such as frame, input and output links, and actuators, are evaluated, characteristic patterns of interest may be potentially revealed. Presented below are suggested a small set of *local features* along with their respective definitions:

- *Vertex Degree*: The count of adjacent edges (i.e., neighboring vertices) connected to a vertex.
- *Vertex Eccentricity*: The maximum shortest distance between the vertex and any other vertex in the graph, it is a metric that can help in identifying links in mechanisms distanced farthest from other links, thus potentially playing a role in long-distance motion transmission.
- *Vertex Centrality*: The importance of the vertex in a graph is measured according to various centrality metrics (RODRIGUES, 2019).
 - *Degree Centrality*: The simplest of measures, identical to the vertex degree. It operates on the premise that vertices of importance possess numerous connections. Within the mechanism's graph representation, it correlates to the number of joints linked to a link and has a direct association with link assortments (Section 2.3.2.2).
 - *Closeness Centrality*: The average distance of the vertex to all other vertices, this metric assumes that vertices of importance are close to other vertices. Within the mechanism graph, it might be indicative of links required to transmit power transmission over shorter spans, such as input links.
 - *Betweenness Centrality*: The extent to which the vertex lies on the shortest paths between pairs of other vertices in a graph. This can reveal the importance of links serving as bridges between disparate sections of the mechanism.
 - *Eigenvector Centrality*: Derived from the principal eigenvalue correlated to the vertex in the adjacency matrix's eigenvector, it assumes a vertex's importance based on the importance of its surrounding neighborhood. Links with elevated eigenvector centrality within the mechanism graph might be key components in the mechanism's efficiency.
 - *Katz Centrality*: An eigenvector centrality variant, it measures a vertex's relative influence within a graph, factoring in both immediate and secondary degree neighbors. Within the mechanism graph, it might reflect the aggregated influence of links directly and indirectly tethered to a given link. For instance, a link with high Katz centrality might substantially affect the mobility of neighboring links, thus being important to the control of the mechanism.

The aforementioned list is not exhaustive. Depending on the distinct mechanism under consideration, the exploration and assessment of supplementary metrics and properties can provide invaluable insights.

4.3.1.2 Global features

Global features refer to measures related to the entire topology of the mechanism. A selection of *global features* is proposed below, along with their respective definitions (STEEN, 2010):

- *Planarity*: A graph is termed planar when it can be embedded in a plane without any edge intersections. Such a characteristic might be relevant for mechanisms requiring spatial arrangements avoiding intersecting links, like planar robotic arms or linkages used in manufacturing systems.
- *Average Degree*: This is the mean adjacency degree of vertices in a graph. For instance, the average degree may provide insights on the complexity of mechanisms.
- *Density*: Defined as the relative ratio of the number of existing edges to the total potential edges among all vertices, this metric describes the graph's degree of interconnectedness. For mechanisms, density may aid in determining the degree of component interconnectivity and interdependency.
- *Diameter*: Representing the greatest shortest distance between any two graph vertices, this quantifies the largest eccentricity value of a vertex in the graph. In the context of mechanisms, the diameter may offer insights into the efficiency of power transmission.
- *Radius*: This quantifies the least eccentricity value of a vertex, representing the center of the graph. Within mechanisms, a smaller radius might indicate quicker responses, whereas a larger one could hint at increased redundancy.
- *Average Clustering*: This metric involves the extent to which graph vertices tend to cluster together. For mechanisms, average clustering can spotlight clusters or groups of links with strong interconnections.
- *Average Shortest Path Length*: This is the average of the minimum count of edges that need to be navigated to go from one vertex to another in the graph. It can be applied to analyze the efficiency of power transmission within the mechanism.
- *Network Complexity Coefficient*: Calculated as the ratio of the variance in the degree distribution to the graph's average degree, this metric becomes more pronounced with an increase in the variability of vertex degrees (BARABÁSI; PÓSFAL, 2016). Such a coefficient can be used to quantify complexity within mechanisms.

To further enhance the data, other features can be assessed to capture nontrivial information about mechanisms (NEWMAN, 2010). The main objective here is to improve the description of mechanisms through the datasets by incorporating valuable new

insights into the characteristics of the mechanisms under study.

4.3.2 Dictionary of Features

The creation of a dictionary of features is suggested in order to standardize and organize the datasets effectively. The aim is to identify and provide comprehensive descriptions for the features that will be evaluated in the mechanisms under study. Following, a structure for the dictionary is proposed:

- *Feature Name*: Name of the feature as a variable in the database.
- *Description*: A brief explanation detailing the significance or purpose of the feature.
- *Rule or Equation*: Mathematical or logical relations explaining how to obtain the feature.
- *Feature Type*: Representation of the feature type, e.g., *textual*, *categoric*, *numeric*, or *time series*.
- *Data Type*: Specification of data storage format, e.g., *string*, *int*, *float*, *bool*, or *datetime*.
- *Boundaries*: Limits in which the feature's value can lie, detailing the *lower and upper bounds*.
- *Example*: A practical instance or use-case scenario showcasing the feature's application.
- *Machine Scope*: Feature level in a machine hierarchy breakdown (Fig. 10), whether it's a *machine*, *mechanism*, *kinematic chain*, *joint*, *link*.
- *Requisite Scope*: Inherent essence of the feature requirement, whether it's a *structural*, *functional*, or *technical*.
- *Requisite Type*: Classification of design requirements into *property* for inherent attributes, *metric* for measurable assessments, and *information* for additional context.
- *Knowledge Domain*: Research field or domain the feature belongs to, e.g., *information retrieval*, *mechanism design*, *graph theory*, or *data mining*.
- *Acquisition*: Method of obtention of feature's data, whether it's *measured*, *calculated*, *inferred* (based on other features), or *implied* (based on intuition).

For ease of reference and effective documentation, it's recommended to implement this dictionary in a spreadsheet format in the project.

4.3.3 Data Evaluation

The *Data Evaluation* step aims to calculate the value of all features listed in the dictionary for each mechanism instance. Their values must be evaluated according to the defined rules or equations and following the data type and the specified units. To accomplish this, the collected data from each mechanism in the datasets must be read, converted into the chosen representation model (e.g., graphs), and appropriate libraries can be used to evaluate the features.

Python (FOUNDATION, 2023) is the most popular programming language for data science (CARBONNELLE, 2023) and offers several specialized libraries, including:

- *Pandas*: Data structures for statistical computing (MCKINNEY, 2010)
- *NumPy*: Array programming for accessing, manipulating and operating on data in vectors, matrices and higher-dimensional arrays (HARRIS et al., 2020).
- *SciPy*: Numerical routines for solving a wide range of scientific problems, including optimization, integration, interpolation, and differential equations. It provides specialized data structures and is built on top of NumPy (VIRTANEN et al., 2020).
- *NetworkX*: Package that enables the exploration, analysis, and calculation of network properties in various scientific fields through a variety of data structures and graph algorithms (HAGBERG et al., 2008).
- *Matplotlib*: 2D graphics package used for application development, interactive scripting, and publication-quality image generation across user interfaces and operating systems (HUNTER, 2007).
- *Seaborn*: Dataset-oriented API for creating statistical graphics, automating the mapping of data values to visual attributes, performing statistical transformations, and enhancing plots with informative labels and legends (WASKOM, 2021).
- *SciKit-Learn*: State-of-the-art machine learning algorithms accessible to non-specialists through a general-purpose high-level language, is suitable for medium-scale supervised and unsupervised problems (PEDREGOSA et al., 2012).
- *Statsmodels*: Extensive tools for statistical modeling and hypothesis testing, including linear and non-linear models, statistical tests, and data exploration, making it integral for econometrics, statistical analysis, and data science (SEABOLD; PERKTOLD, 2010).
- *SageMath*: Open-source mathematics software system that integrates several libraries and packages into a unified interface, providing a comprehensive environment for advanced algebra, calculus, and various other domains of mathematics (DEVELOPERS, 2023).

- *Orange*: Open-source data visualization and analysis tool for both novice and expert users, offering a range of components for machine learning and data mining through a visual programming interface (DEMŠAR et al., 2013).

Once all instances have their enriched features been evaluated, storing the data in a database becomes essential for further analysis.

4.3.4 Database

The mechanism *Database*, the output of Phase 2, refers to the structured organization and storage of the collected and enriched data. There is a wide range of formats for databases, from simple flat table to specialized systems to record data (HAN et al., 2012). Independently of their complexity, the database must ensure data integrity, facilitate efficient retrieval, and serves as the foundational layer upon which analytical algorithms operate to extract meaningful patterns and insights.

Considering the diverse landscape of database structures, for many academic projects, a simpler database structure such as a flat table (Eq. (46)) might suffice. Flat tables are straightforward, easy to understand, and often more than adequate for datasets that do not require complex relationships or queries. Their simplicity ensures faster data retrieval times, minimalistic design, and often easier data management. Additionally, flat tables can be directly imported into a multitude of statistical software, facilitating quick and seamless analysis.

4.4 PHASE 3: FEATURE ANALYSIS

The phase 3, *Feature Analysis*, focuses on identifying the optimal subsets of most relevant features for further gap discovery. Four steps comprise this phase:

1. DATA CLEANSING: Correction of the database by handling possible issues to ensure data consistency for further analysis.
2. DATA INSIGHTS: Exploration of the database by applying statistics to summarize the main characteristics and getting insights into data.
3. STRATEGY ANALYSIS: Formulation of data mining strategy procedures for attending to the study goals (Section 4.2.1).
4. FEATURE SELECTION: Identification of the minimal features to represent the most relevant design requirements throughout the strategies.

The output of phase 3, based on the chosen strategies, yields subsets of essential features that best represent the design requirements for each study goal.

4.4.1 Data Cleansing

The first step in the feature analysis is Data Cleansing, which aims to verify and correct possible issues with inconsistent data. Among the most important factors for the quality of data, [Han et al. \(2012\)](#) highlights: accuracy, completeness, consistency, timeliness, believability and interpretability. Organizing and cleaning the data ensure its quality and reliability, helping to eliminate any inconsistencies or errors in the dataset.

The main work involves cleaning routines to check data type, handle missing values and outliers, and removing duplicates in instances (rows) and features (columns).

Validating the data types of features is very important in the data evaluation process. For instance, if a feature is expected to contain numerical values, it is imperative to ensure that all values are indeed numeric. In cases where a feature has a different data type than expected, appropriate methods for data type conversion should be applied to guarantee consistency within the dataset.

Handling missing values is another critical aspect of data evaluation, and several techniques can be employed ([HAIR et al., 2019](#)). If the amount of missing data is relatively small compared to the overall dataset, one approach is to remove the instances containing missing values. Similarly, if a significant portion of a feature's values are missing, removing that feature might be necessary. Alternatively, missing values can be imputed using statistical measures, such as mean, median, or mode, when the number of missing values is relatively small or removing them would result in a significant loss of information.

Duplicated features or instances can also present challenges during data evaluation. To address duplicated features, it is important to check for identical column names and compare the values within each column. In case of identical values, the duplicated columns must be removed from database.

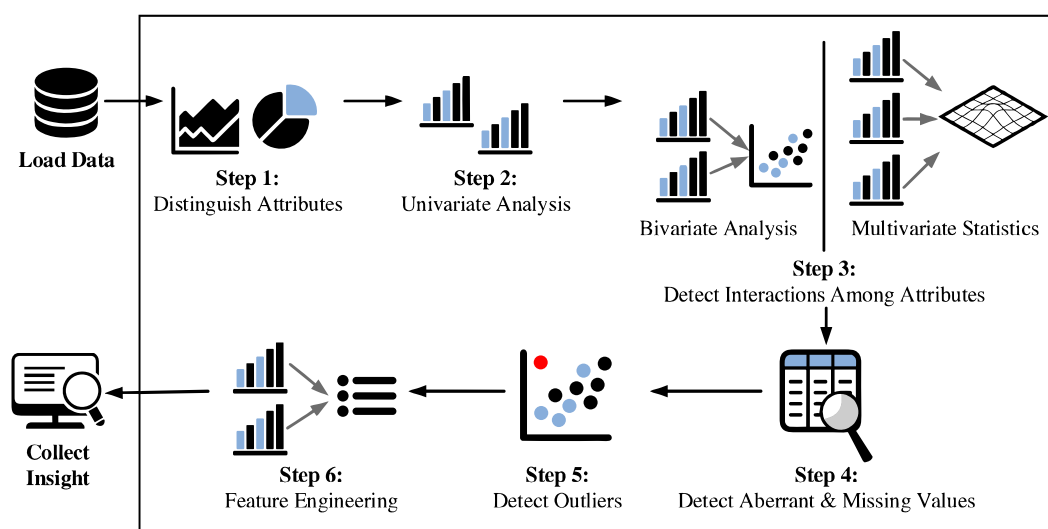

Duplicated instances occur when multiple records in the dataset have the same values across all features. In case of mechanisms represented by graphs, it is crucial to detect these duplicates as they can represent isomorphisms ([Section 2.3.2.4](#)). The appropriate course of action is removing or consolidating duplicate instances into a single representative instance. There are several methods for checking for isomorphism such as VF algorithm ([JÜTTNER; MADARASI, 2018](#)), graph edit distance ([ABU-AISHEH et al., 2015](#)), graph kernel hashing ([SHERVASHIDZE et al., 2011](#)), perimeter loop ([DING; HUANG, 2009](#)), among others.

This step requires significant time and necessitates meticulous manual review by the engineer.

4.4.2 Data Insights

The second step in feature analysis is an exploratory data analysis (EDA) aiming to improve understanding on existing data by performing statistical analysis (KOMOROWSKI et al., 2016). Visual methods are often used to support three main approaches: descriptive (univariate), correlative (bivariate) and contextual analysis. The latter involves events that are time or agent based, not being related to the scope of this study. A general EDA process steps are exemplified in Figure 38.

Figure 38 – Example of an EDA process.

Source: Ghosh et al. (2018).

The descriptive analysis, often referred to as univariate analysis, focuses on summarizing the main features of a single variable in a dataset. This approach seeks to provide insights into the central tendency, spread, and shape of the data distribution. While measures like mean, median, and mode convey the data's central position, the variance, standard deviation, and range delineate its spread. Additionally, the shape of the distribution is characterized by attributes like skewness and kurtosis. Testing normality is vital for determining appropriate statistical methods and for selecting measures of central tendency and dispersion in continuous data (MISHRA et al., 2019). For small sample sizes ($n < 50$), the Shapiro–Wilk test is recommended due to its superior power in detecting non-normality. However, for sample sizes of at least 50, various methods and visualizations like the Kolmogorov–Smirnov test, histogram, box plot, P–P Plot, Q–Q Plot, and others can be employed to assess data normality. In Table 13, some of the most useful univariate analysis is presented for the attribute type, including visualization charts.

The correlative analysis is concerned with understanding the relationships or associations between two or more variables in a dataset. This approach employs measures like Pearson's correlation coefficient r to quantify linear relationships between

Table 13 – Common univariate analysis according to feature type.

Attribute type	Statistic/Calculation	Details	Visualization
Categorical	Cardinality	Number of unique values for the categorical attribute	Bar plot
	Unique counts	Number of occurrences for each unique value of the categorical attribute	Stacked bar
Numerical	Quantile statistics	Q1, Q2, Q3, min, max, range, interquartile range	Boxplot, Violin plot
	Descriptive statistics	Mean, mode, standard deviation, median, absolute deviation, kurtosis, skewness	Histogram, Line
	Distribution	Based on the appropriate number of bins	Histogram

Source: Adapted from [Shixin \(2020\)](#).

paired variables. Visual aids, such as scatter plots, play a pivotal role in visually assessing the nature and strength of these relationships. When examining multiple variables, heatmaps of correlation matrices can provide a holistic view of inter-variable relationships ([BRUCE et al., 2020](#)). Additionally, significance testing methods, like the t -test for correlation coefficients, help determine the statistical significance of observed correlations. For non-linear or monotonic relationships, alternative correlation measures such as Spearman's rank ρ or Kendall's τ coefficient might be employed ([LEWICKI; HILL, 2006](#)). In [Table 14](#), some of the most useful univariate analysis is presented for the attribute type, including visualization charts.

Table 14 – Common bivariate analysis according to feature type.

X	Analysis	Y	
		Categorical	Numerical
Categorical	Qualitative	Contingency table with unique counts of X per unique value of Y	Descriptive statistics or histogram of Y per unique value of X
	Quantitative	Chi-square test Information gain	Student T-test ANOVA Logistic regression <i>Discretize Y</i>
Numerical	Quantitative	Student T-test ANOVA Logistic regression <i>Discretize X</i>	Correlation Linear Regression <i>Discretize X and Y</i>

Source: Adapted from [Shixin \(2020\)](#).

This is a foundational step in the data analysis process, offering critical insights into the nature and structure of data, guiding further analyses, and assisting in hypothesis generation and testing.

4.4.3 Strategic Analysis

Once the database has been prepared, explored, and characterized, the third step in the feature analysis phase is focused to the formulation of precise data mining

strategies that align with the objectives of the study. Three main components structure each strategy: a clearly defined objective, a systematic procedure, and a robust evaluation protocol.

The *objective* should articulate the central question or challenge of the data analysis, providing a clear achievement.

The *systematic procedure* constitutes a detailed, step-by-step pipeline, which demonstrates the sequence of tasks and methods to be used. This procedure ensures clarity and offers reproducibility.

The *evaluation protocol* is determined using relevant metrics, such as scores or significance levels. These metrics should be statistically significant and hold practical value (HAIR et al., 2019). The use of visual tools is suggested to augment the understanding of the results.

Employing this systematic method ensures that the strategy analysis is both comprehensive and reproducible, and it is firmly rooted in data science principles.

To guide the search for gaps with potential for innovation in mechanism design requirements, it is first essential to map existing mechanisms comparatively. This map assists in evaluating areas with innovation potential and subsequently determining the most critical project requirements. The technology boundary chart (Fig. 28), as referenced in Karhula and Nicolai (2018), serves as a beneficial tool in this context. Therefore, at this stage, the creation of a technological map comparing the capabilities and complexities of the database mechanisms is recommended. Other attributes might be considered to segment the data using symbols, colors, and the size representation of each mechanism on the technological map.

Analysis of the map allows for the identification of the technological frontier that distinguishes the area of existing mechanisms in the database from the disruptive innovation region. Generally, potential for disruptive innovation increases when moving left (reducing complexity) and upwards (increasing capability). Furthermore, it is possible to identify subregions within the technological frontier where mechanisms are absent, indicating local innovation potential.

Database analysis strategies should be crafted with the aim of assisting in identifying the most relevant design requirements in the technological map regions with the highest innovation potential.

4.4.4 Feature Selection

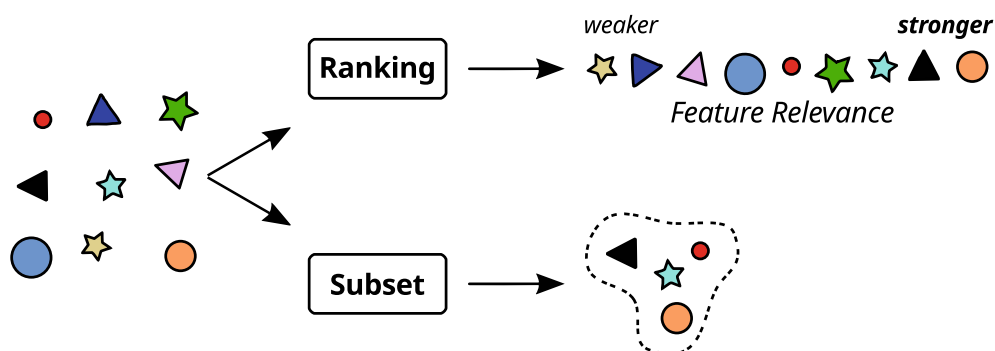

In the fourth step, key features in mechanism design should be identified through the application of strategies. Algorithms for Feature Selection (FS) aid in determining a subset of the most pertinent and informative features from the original dataset (LIU; MOTODA, 1998b), thereby reducing dimensionality and enhancing interpretability (GUYON; ELISSEFF, 2003). The goal is to identify a concise set of features that best represent

the most important design requirements, aiding in the identification of innovation gaps.

The relevance of a feature is determined by the characteristics of the data, not by its value (VENKATESH; ANURADHA, 2019). A feature is termed *relevant* if its removal leads to a deterioration in the performance measure of the remaining features (LIU; MOTODA, 1998a). A *strongly relevant* feature becomes indispensable for an optimal subset, and its absence would change the original conditional class distribution. Conversely, a *weakly relevant* feature may not always be vital, but under certain circumstances, it becomes essential for an optimal subset. Notably, a weakly relevant feature is deemed redundant if correlated entirely with another feature (YU; LIU, 2004). An *irrelevant* feature has no necessity.

Methods of feature selection can be categorized in two manners. The first categorization relates to the output (Fig. 39): either a ranked list of all features by relevance, termed Feature Ranking (FR), or a subset of relevant features, termed Subset Search.

Figure 39 – Categories of Feature Selection output.

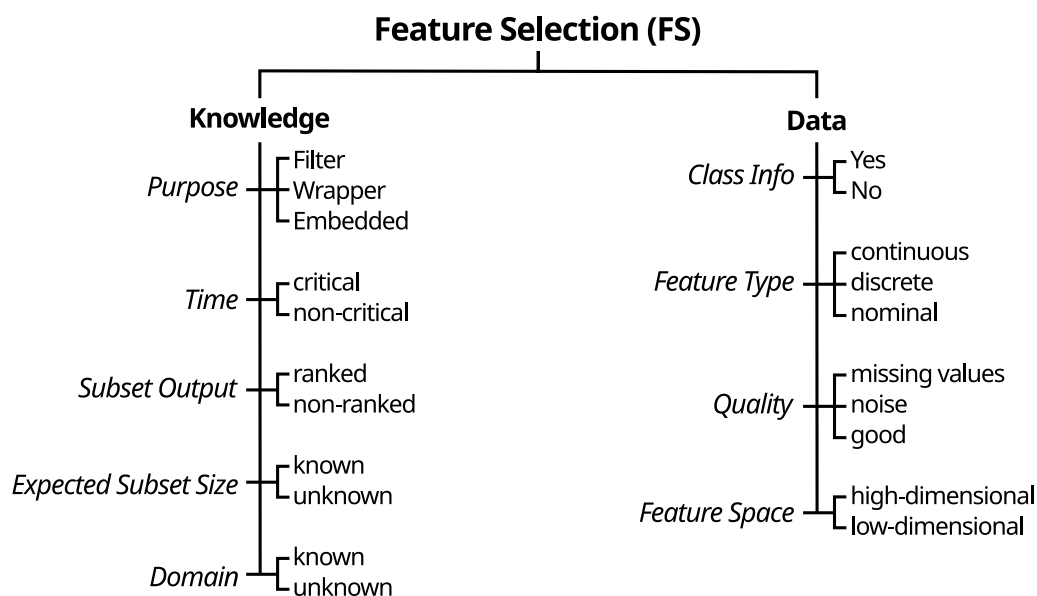

Source: Adapted from Bolón-Canedo and Alonso-Betanzos (2018).

The second categorization is based on the inductive learning method used to infer a model, encompassing three primary methods (BOLÓN-CANEDO; ALONSO-BETANZOS, 2018; SAHU et al., 2018):

- *Filter*: Evaluates features using statistical metrics such as correlation and mutual information, independent of a learning model (unsupervised).
- *Wrapper*: Evaluates feature subsets by training them on a supervised learning model and then measuring its performance. Examples include recursive feature elimination (RFE) and genetic algorithms. Though more accurate than filter methods, they are computationally demanding.
- *Embedded*: Combines an independent measure within the training of the supervised learning model. Techniques like Lasso or Ridge regressions and Random Forest are employed. It often outperforms other methods, being less resource-intensive than wrapper methods but remains model-specific.

Given the multitude of algorithms available for feature selection, a categorization was proposed by Liu and Yu (2005) from a user's perspective, as depicted in Figure 40.

Figure 40 – User's perspective categorization for FS methods.

Source: Adapted from [Liu and Yu \(2005\)](#).

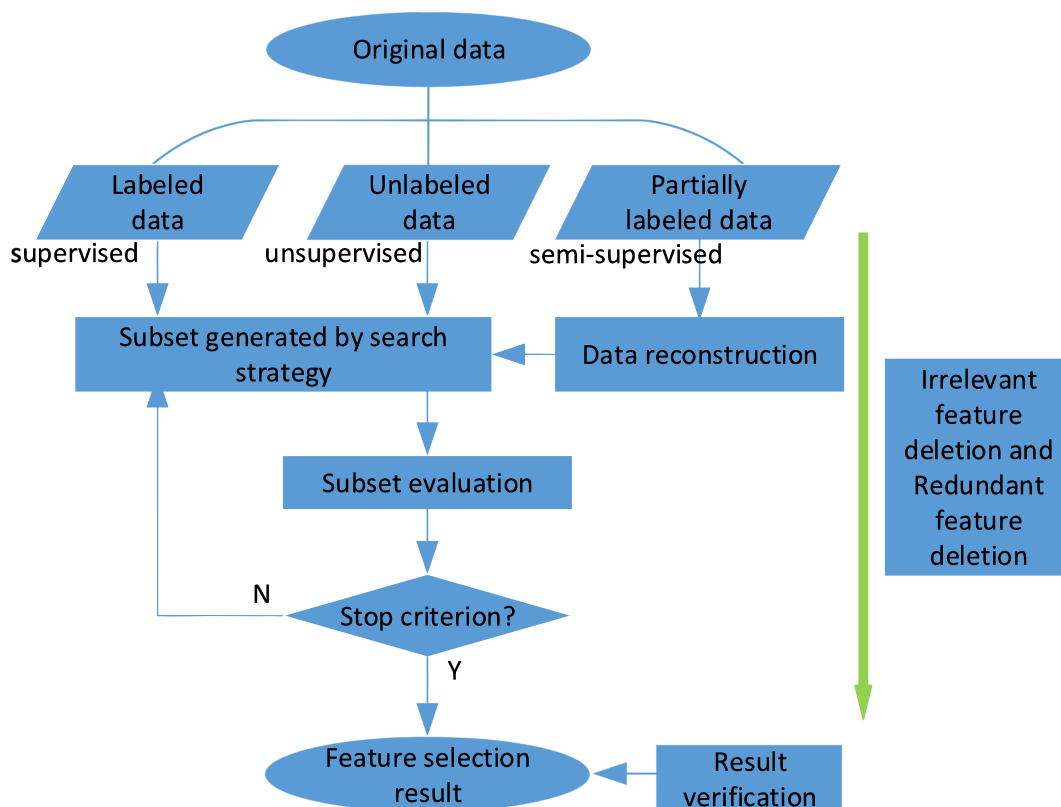

Feature selection methods are useful in enhancing knowledge discovery, particularly in high-dimensional data contexts, where there are as many or more features as instances. However, the challenge lies in selecting the optimal FS method. [Khalid et al. \(2014\)](#) conducted a comparative analysis of nine distinct feature selection algorithms. Their findings indicated that most methods address the elimination of redundant or irrelevant features in isolation, with only a few considering noisy data. In their work, [Chandrashekar and Sahin \(2014\)](#) introduced FS techniques predominantly associated with supervised learning models. They further integrated Sequential Feature Selection (SFS) methods with classification models such as the Support Vector Machine (SVM) and Radial Basis Function Network (RBF).

[Chen et al. \(2020\)](#) executed an evaluation on three high-dimensional datasets using three feature selection (FS) methods: Random Forest (RF), Recursive Feature Elimination (RFE), and Boruta. They compared the accuracy and performance of four classification models: RF, SVM, K-Nearest Neighbors (KNN), and Linear Discriminant Analysis (LDA). RF was found to be the superior model due to its simplicity, ability to handle both categorical and numerical features, and lack of distribution assumptions.

Evolutionary computation for FS has garnered attention, with methods like genetic algorithms (GA), genetic programming (GP), and particle swarm optimization (PSO) being at the forefront ([XUE et al., 2016a](#)). [Cai et al. \(2018\)](#) not only discussed evaluation measures for feature selection but also surveyed methods across supervised, unsupervised, and semisupervised domains. They presented these methods within a unified framework ([Fig. 41](#)). Ensemble methods, which involve the integration of multiple

models, have shown promise in augmenting predictive performance (BOLÓN-CANEDO; ALONSO-BETANZOS, 2018). Techniques like boosting and bagging of inductive learning models have been employed to enhance accuracy and stability over singular FS methods. Given the myriad of potential ensemble structures, numerous studies have aimed to compare and recommend optimal combinations (KIZILOZ, 2021; SPOONER et al., 2023). Some research efforts have also focused on creating frameworks to refine the FS process. For instance, Georges et al. (2020) introduced the *FS-Select* framework to pinpoint optimal feature selection methods, while Overschie et al. (2022) developed a benchmarking platform named *fseval* for comprehensive comparisons and validations of Feature Ranking and Feature Selection algorithms.

Figure 41 – Unified framework view of FS methods.

Source: Adapted from Cai et al. (2018).

A review of the literature was conducted, and the robustness of ensemble-based methods in feature selection is evident. Given the nature of mechanism design data, strategies capturing both linear and non-linear relationships among features, while also addressing potential feature interactions, are essential. Despite the numerous possibilities, a basic ensemble setup for Feature Selection is suggested as follows:

- **Models**

- *Random Forest (RF)*: Recognized for its ability to provide feature importance metrics, this method adeptly captures non-linear relationships.

- *Gradient Boosted Trees*: Supplementing RF, these models offer distinct importance scores due to their sequential learning mechanism, which focuses on previously mispredicted instances.
- *Recursive Feature Elimination (RFE) with Logistic Regression or Linear SVM*: Inherently, linear models discern linearly separable patterns. Particularly, **RFE** ranks features based on their coefficients in the linear model.
- *Lasso Regression*: Due to its regularization attributes, this method selects a subset of features by reducing certain coefficients to zero.

- **Ensemble Aggregation**

- Features can be ranked by majority voting, summing their importance scores from both tree-based and linear models. Higher aggregate scores indicate features consistently considered as important across methods.

- **Evaluation**

- Model performance with selected features can be validated using a test set or cross-validation to ensure feature generalizability.

In summary, for the domain of mechanism design, an ensemble-based approach for feature selection can aid in determining the most relevant features related to design requirements. The proposed ensemble setup provides a harmonious blend of methods, ensuring an exhaustive exploration of the feature space. Iterative refinement is essential as research progresses, ensuring alignment with the characteristics of the studied mechanism.

The output of this phase 3 yields optimal features' subset that aligns with the research goals for further analysis to discover potential innovative gaps within their values.

4.5 PHASE 4: GAP DISCOVERY

The final phase, called *Gap Discovery*, aims to uncover innovative requirements for new mechanism designs by identifying gaps in existing features. Comprising four steps, this phase elucidates the process of systematically discovering and leveraging these gaps:

1. **GAP SEARCH**: Examine features to identify gaps, i.e., non-existent values or intervals in database.
2. **GAP ANALYSIS**: Evaluate and rank gaps in features based on their potential for innovation.
3. **GAP CLUSTERING**: Aggregate gaps to form meaningful clusters.
4. **INNOVATION SETS**: Select promising gap clusters to derive innovation sets for new design requirements.

4.5.1 Gap Search

The *Gap Search*, as the initial step in Gap Discovery, examine mechanism features to identify gaps, defined as values or intervals missing on database. This step adopts a comprehensive procedure to analyze features in desired contexts, ensuring an exhaustive exploration of the data landscape.

A custom Python function, outlined in [Algorithm 1](#), was developed to systematically scan each feature in the dataset, classifying them by data type and uncovering gaps. This inclusive process encompasses both global and local contexts, facilitating an in-depth data examination.

Algorithm 1 Gap Search for Features

```

1: procedure GAPSEARCH(database)
2:   results  $\leftarrow$  {}
3:   for each feature in database do
4:     Detect data_type of feature
5:     if data_type is numeric then
6:       database_rounded, precision  $\leftarrow$  ROUND_ARRAY(feature.dropna().unique())
7:       Update data_type if necessary
8:       Identify lower_bound and upper_bound of database_rounded
9:       if data_type is integer then
10:        eps  $\leftarrow$  1
11:       else if data_type is float then
12:        eps  $\leftarrow$   $10^{-precision}$ 
13:       end if
14:       Calculate difference between each adjacent element of database_rounded
15:       if any value in difference > eps then
16:        Identify gaps using the indices where difference > eps
17:        Store these gaps
18:       end if
19:       Update results with the details for the numeric feature
20:     else
21:       List unique items in the non-numeric feature
22:       Update results with the details for the non-numeric feature
23:     end if
24:   end for
25:   return results
26: end procedure
27: procedure ROUND_ARRAY(arr)
28:   Get unique values of arr and sort them
29:   Identify the number of unique values in arr
30:   if all values in arr are integers then
31:    return sorted integer values of arr, 0
32:   end if
33:   Find smallest decimal value to round arr while maintaining unique values
34:   Round arr using this decimal value
35:   return rounded_arr and precision
36: end procedure

```

For each considered feature, the function distinguish its data type and, for numeric features, refines values to the smallest representable increment. This precision approach is essential for accurately detecting gaps. The function also check the lower and upper data bounds and computes differences between adjacent elements for numerical features, thereby identifying missing intervals.

The algorithm's output is a structured summary of each feature, detailing its type, unique elements, and observed gaps. Additionally, it provides a quantification of

features with gaps, offering a comprehensive overview of areas lacking data.

4.5.2 Gap Analysis

Following, *Gap Analysis* step focus on prioritizing gaps based on essential ranking criteria including:

- Global context presence, indicating gaps that are unrepresented intervals in database existing designs.
- Association with features of elevated design importance, particularly those with a property requisite type and high relevance in local contexts.
- Correlation with features that simplify complexity or augment capabilities.
- Recurrence across analyses, emphasizing prevalent gaps.

A custom Python function was developed to process and rank gaps, integrating data from diverse contexts such as global mechanism and local links and joints. This procedure creates a dataset connecting each gap to its respective feature, incorporating attributes like repetition count, global context occurrence, scope, and correlations with complexity and capability enhancement.

The result is an ordered list of gaps, ranked by their importance. This list is useful in identifying innovation opportunities for new mechanism designs. Special emphasis is placed on gaps related to features with 'property' requisite type, acknowledging their essential design role.

This systematic approach ensures the identification of most relevant gaps, guiding subsequent steps towards reaching these intervals. It promotes informed design of new mechanisms by focusing on intervals with greatest potential for innovation and improvement.

4.5.3 Gap Clustering

Gap Clustering step involves categorizing identified gaps into clusters based on their context and importance. This step consolidates insights from Gap Analysis into actionable clusters, informing innovative design strategies.

This phase transforms abstract Gap Analysis findings ([Section 4.5.2](#)) into structured groupings. Clustering gaps by shared contexts such as global mechanisms, local market status, or specific design parameters, establishes a comprehensive understanding of unexplored innovation areas in mechanism design.

The process employs combinatorial methods for exhaustive gap combinations, targeting groupings that indicate significant mechanical advancements. The outcome is a set of distinct clusters, each embodying a unique combination of identified gaps. These clusters assist engineers and designers in the decision-making process by em-

phasizing areas of mechanism design that hold the greatest potential for groundbreaking innovation.

4.5.4 Innovation Sets

The last step, *Innovation Sets*, consists on selecting the most relevant feature gap subsets within each cluster. This method aims to optimize innovation potential by selecting viable independent sets, based on an in-depth analysis of feature interdependencies.

Innovation sets are derived by ranking these independent sets according to a predefined analytical strategy. These top-ranked sets, referred to as innovation sets, are potential sources for generating innovative design requirements for new mechanisms.

The output of this phase comprises design requirements derived from the innovation sets. By aligning with existing mechanisms in the database, these requirements offer valuable insights for potential innovations, contributing significantly to the advancement of new mechanism designs.

5 PROCESS APPLICATION IN AUTOMOTIVE PGMS DATABASE

This chapter explores the application of the process, as proposed in [Chapter 4](#), for identifying innovative gaps within the database of automotive Planetary Gear Mechanisms. The study focuses on the analysis of automotive planetary gear trains with six to ten speeds, examining their features to determine requirements for innovation. Each phase of the process is exemplified through selected samples, and the resulting findings are presented and discussed in detail.

A total of seven innovation sets have been identified, each representing a promising avenue for the development of new and innovative Planetary Gear Mechanisms. These sets address the identified gaps and capitalize on the potential inherent in each context. The chapter culminates in a thorough discussion of these innovation sets, providing insights into future directions for PGM development in the automotive industry.

5.1 APPLICATION: AUTOMOTIVE PGMS FOR PASSENGER CARS

In this section, the proposed process ([Fig. 34](#)) is applied to discover potential innovative gaps in automotive PGMS of passenger cars in the range of 6 to 10 gears. The interest lies in answering the following questions:

1. *Is it possible to identify potential innovation opportunities for the design requirements of an extensive and diverse database of PGMS for passenger cars automatic transmissions in a range of 6 to 10 gears?*
2. *What are the main "property" features that distinguish commercial mechanisms from those patented but not yet built?*
3. *What "property" features distinguish PGMS based on their total number of PGSs?*
4. *What "property" features distinguish PGMS based on their number of forward gears?*
5. *What are the most promising innovation sets for the design requirements of new PGMS?*

The step-by-step application of the four phases of the proposed process is presented in the following sections.

5.2 PHASE 1: MECHANISM SURVEY - PGMS

5.2.1 Step 1. Study Goals

In alignment with the objectives outlined in the thesis ([Section 1.1](#)), and highlighted in the previous section, the study goals can be summarized as follows:

1. **Mechanism Type:** The focus is on planetary gear mechanisms in automotive automatic transmissions.
2. **Main Goal:** The main objective is to identify potential innovation opportunities in the topology design requirements of PGMs for automatic transmissions in passenger cars.
3. **Specific Objectives:**
 - (a) Identify the most relevant features of planetary gear mechanisms with six to ten gears.
 - (b) Identify the most relevant features of commercial automatic transmissions.
 - (c) Identify the most promising innovation sets for different automatic transmission design contexts.
4. **Data:** The analysis must include sources such as patented data, academic articles, and manufacturer reports.
5. **Scope:** The study focuses on transmissions with six to ten gears, specifically for passenger cars.
6. **Constraints:** PGMs and their associated kinematic chains will be represented as graph models described in [Section 3.1](#).
7. **Evaluation Criteria:** The evaluation will be based on gaps identified in a database of over one hundred mechanisms.

5.2.2 Step 2. Data Collection

The data was primarily collected from patent databases, particularly ESPACENET, along with books, academic articles, and manufacturers' technical manuals related to automatic transmissions.

To gather relevant information on automotive automatic transmissions with 6 to 10 forward speeds, a patent search was conducted using diverse criteria. The search was performed on ESPACENET, a recognized worldwide open database, as it provided more consistent and comprehensive results when compared to other databases such as PATENTSCOPE, USPTO, and Google Patents. The search query used was as follows:

```
((nftxt = "automatic" OR nftxt any "multi speed")
AND (nftxt = "transmission" OR nftxt = "gearbox")
AND pd <= "2023-03-20")
AND ((ipc =/low "F16H3/66" OR ipc =/low "F16H3/44"
OR ipc =/low "F16H3/62") AND cpc =/low "F16H2200"))
NOT ((ti any "electric*" OR ti = "hybrid"
OR ti=("method" prox/distance<5 "operation"))
```

```
OR (cpc = "F16H3/724" OR cpc = "F16H3/727"  
OR cl = "F16H2057/02034" OR cl =/low "H02K7/00"  
OR cl =/low "B60K6/20" OR cl =/low "B62"  
OR cl =/low "F16K" OR cl =/low "G06F"  
OR cl =/low "B60W" OR cl =/low "F15B"))
```

The search query includes specific criteria, such as the terms "automatic" or "multi-speed" in combination with "transmission" or "gearbox," limited to patents published before March 20, 2023. Additionally, International Patent Classification (IPC) and Cooperative Patent Classification (CPC) symbols related to automatic transmissions were used, and certain exclusions were applied to filter out irrelevant patents, as listed below:

- Specific IPC codes were used to *refine the search*:
 - IPC symbols included "F16H3/66" (Controlled change-speed gears), "F16H3/44" (Epicyclic or planetary gearings), and "F16H3/62" (Multiple forward speeds).
 - CPC symbol "F16H2200" (Automatic control in gearings) was utilized to further refine the search.
- To exclude irrelevant patents, specific *exclusion criteria* were applied:
 - These criteria involved excluding patents related to electric or hybrid technologies.
 - CPC symbols ("F16H3/724" - Electric or hybrid drive, "F16H3/727" - Continuously-variable gearings).
 - IPC symbols ("F16H2057/02034" - Electric propulsion with power supplied within the vehicle, "H02K7/00" - Arrangements for handling mechanical energy structurally associated with the machine, "B60K6/20" - Arrangement or mounting of plural diverse prime-movers, "B62" - Land vehicles, "F16K" - Valves, "G06F" - Electric digital data processing, "B60W" - Conjoint control of vehicle sub-units, "F15B" - Systems acting by means of fluids).

Further filtering was performed to narrow down the search results based on the number of forward speeds:

- *Number of Forward Speeds (CPC code)*:
 - 6 forward speeds: F16H2200/0052
 - 7 forward speeds: F16H2200/0056
 - 8 forward speeds: F16H2200/006
 - 9 forward speeds: F16H2200/0065
 - 10 forward speeds: F16H2200/0069

The patent search returned 3125 published patents relating to 6 to 10 forward speeds automotive automatic transmissions, published between 1925 and 2022. The

resulting data was stored in a Google Sheets spreadsheet in Google Drive. In particular, the annual number of patents in the results showed an average of 200 applications between 2002 and 2017. However, there was a peak of 295 patents in 2007, of which 219 were from GM, which was the highest number of applications during this period. There was then a decline after 2017, possibly due to the increased popularity of hybrid and electric vehicles, which may have shifted the focus of innovation towards transmissions for these types of vehicles. A chart of annual patents for automatic transmissions for cars is shown in [Figure 42](#).

Figure 42 – Automotive PGM patents published per year.

Source: Author.

Identifying all mechanisms protected by a single patent is a laborious task, as patents typically claim a family of mechanisms. Nevertheless, it is possible to estimate the minimum number of PGMs protected by each patent by examining their CPC code related to the number of forward gears. Based on this analysis, it was found that 734 patents claimed 6-speed transmissions, 445 patents covered 7-speed transmissions, 1,009 patents referred to 8-speed transmissions, 710 patents included 9-speed transmissions, and 693 patents were associated with 10-speed transmissions. This data suggests a minimum of 3,591 possible mechanisms. However, it is essential to note that patents may not always indicate all classification codes covered by them, making this analysis an estimate of the minimum number of mechanisms with a specific number of forward gears.

[Figure 43](#) provides a visualization of the yearly patent applications for automotive automatic transmissions, categorized by the number of gears. While there was a slight

increase in patents for 6 and 7-speed transmissions in the early 1970s, the trend gained significant momentum in the early 2000s, with a notable focus on 8-speed transmissions, representing approximately 75% of patented transmissions during the peak in 2007. Subsequently, from 2012 onwards, inventors shifted their focus to increasing the number of gears, leading to more patents for 9 and 10-speed transmissions.

Figure 43 – Automotive PGM published patents segmented by gear ratios (since 1965).

Source: Author.

Furthermore, the analysis of patent applicants (Fig. 44) revealed that GM (USA) and HYUNDAI (South Korea) are the companies with the highest number of patents for automotive automatic transmissions, each accounting for just over 20% of the total patents. This is followed by ZF (Germany) with almost 15% of total patents and AISIN (Japan) with about 5%. FORD (USA), TOYOTA (Japan), and HONDA (Japan) held 3.4%, 2.9%, and 2.4% of the patents respectively. Notably, several universities also patented automatic transmissions for cars, accounting for 1.7% of the total, with China's BEIHANG, ZHAOQING, and CHINA GEOSCIENCES WUHAN universities standing out. Other applicants, with a share of 1.5% or less of published patents, accounted for about 15% of the total.

Based on the results of the patent search, data from 1995 onwards were selected for further analysis, as these years contain the most representative data in terms of patent distribution. Random samples of patents were then selected for each group of forward speeds to ensure a balanced dataset. To complement the dataset, additional samples were selected from other sources such as academic articles and

Figure 44 – Automotive PGM published patents by applicants.

Source: Author.

industry brochures, including commercial transmissions. In total, 51 patents and 15 other sources from 17 different owners were selected for analysis. A meticulous manual analysis of each source was performed to identify and collect data on 160 existing PGMs. A summary of the data collected is presented in [Table 15](#).

Table 15 – Summary of PGMs' collected data.

FWD GEARS	Sources Collected		Owners	PGMs
	Patents	Other Sources		
6	12	3	7	77
7	10	0	6	16
8	15	7	10	24
9	11	3	8	16
10	13	2	8	27
Unique	51	15	17	160

Source: Author.

5.2.3 Step 3. Dataset Creation

For this step, a standard automated dataset template has been developed to convert the collected PGMs data from the previous step ([Section 5.2.2](#)) into suitable graph representations ([Section 2.3.1](#)) for posterior analysis. For reasons of space, the template worksheet is presented in [Appendix A.1](#). It requires manual input of minimal

data to characterize mechanisms in terms of identification, topology, functionality, and technical details. The dataset template was automated to generate the PGM topological graph, and the kinematic chain graph (DBG), evaluate and validate structural and functional characteristics, ensuring data consistency and reliability.

The PGM dataset files were created as spreadsheets in Google Sheets and stored in a dedicated folder in Google Drive. Each spreadsheet represents a source of collected data, which may contain one or more related PGMs. In cases where a source contains multiple mechanisms, they are represented by one spreadsheet with multiple worksheets. Conversely, if a source contains only one mechanism, it is represented by a spreadsheet with a single worksheet. The process of creating each PGM dataset begins with copying the standard template as a new dataset file and manually inputting the mechanism's identification, topology, functional, and technical data.

The application of this method is illustrated by a sample from the collected data, an 8-speed automatic transmission developed by Toyota, shown in [Figure 45](#).

Figure 45 – Toyota 8-speed automatic transmission for transverse application.

Source: Adapted from [Toyota \(2016\)](#).

The dataset is identified based on the data source, such as the patent number or owner name for academic and industry, and the mechanism model, such as the figure number in the source or commercial name. Spreadsheet files are named according to the source, and worksheets are named according to the model of the PGM they represent. The Toyota's 8-speed AT ([Fig. 45](#)) patent publication number is US10563738B2 ([IKEMURA et al., 2016](#)), and an excerpt of its bibliographic data is provided in [Figure 46](#). The PGM is based on 'FIG. 1' of the referred patent and its functional diagram is shown in [Fig. 47](#). From this point, the Toyota's 8-speed PGM is identified by its unique identification as *US10563738B2__FIG_1*. Its input identification data is presented in [Table 16](#).

FIG. 1

Source: Adapted from Ikemura et al. (2016).

The main topological characteristics are identified by analyzing the mechanism's functional diagram (Fig. 47). This process starts with determining the number of elementary PGSs and their classification as simple (S) or double (D). An adopted standard procedure was to label the elementary PGSs, numbering them from the closest to the input joint as PGS1 and sequentially numbering the adjacent PGSs up to the opposite side of the transmission. All the elementary links of each PGS are labeled according

Table 16 – *US10563738B2__FIG_1* input identification data.

to their respective symbols (see [Tables 5a](#) and [6a](#)) along with the additional number of the **PGS** they belong to.

Next, it is reported the inclusion of any additional links in the mechanism beyond the elementary links of the **PGSs**, including frame, input, and output links. Furthermore, any elementary link that belongs to the declared **PGSs** but is not present in the PGM is excluded and indicated with a '-' sign. The compound links (CLs) are then input by listing the elementary links they consist of.

To complete the topological characterization of the PGM, the shifting couplings (SCs) are recorded by indicating each pair of links forming the joints and their classification as clutch (C) or brake (B), followed by sequential numbering. The necessary and sufficient topological input to generate the graph of *US10563738B2__FIG_1* is shown in [Table 17](#). The semicolon character ';' is used to separate entities in the input data, facilitating parsing of the information for automated graph generation. It's worth noting that link labels in [Table 17](#) differ from the existing nomenclature in the diagram of [Figure 47](#), as it follows the standard procedure described above.

Table 17 – *US10563738B2__FIG_1* input topological data.

The required information for the functional characteristics of the PGM involves gear ratios specifications. It's mandatory to input at least the number of forward and reverse (R) gears. If available in the source, the gear ratio values and their respective set of active shifting couplings can also be input in the dataset. [Figure 48a](#) provides the engagement operation sequence, present as 'FIG. 2' in the *US10563738B2__FIG_1*'s

patent, containing the number of gear ratios and the active shifting couplings, but misses additional information. To complete the functional characteristics, the gear ratios values (Fig. 48b) were retrieved from an academic source (AOKI et al., 2013), and input in the dataset as presented in Table 18.

After inputting the required data, the dataset template automatically generates the list of vertices and edges of the topological graph of PGM and the double bicolored graph (DBG) of the kinematic chain. The list of vertices in the mechanism is generated based on elementary links of PGSs (Tables 5a and 6a) and subsequently contracted based on the compound links declarations. In the list is provided a sequential enumeration of all links, beginning with the frame (F) as number 1, the input (IN) as number 2, the output (OUT) as number 3, and so on for the other links.

Next, the list of edges is created based on the elementary joints of PGSs (Tables 5b and 6b) including the comprising pair of links, the characterization of the joint by type and level, and the joint label (for actuators). Each edge is sequentially enumerated, starting with the input joint as number 1, followed by the output joint as number 2, the kinematic chain joints, and finally, the shifting couplings based on the provided sequence. Both graphs are visually presented in Figure 49.

Figure 49 – PGM and DBG graphs of *US10563738B2__FIG_1*.

The structural characteristics (Section 2.3.2.3) are automatically validated by the dataset template, which analyzes the number of loops, revolute and gear joints, and calculates the mobility. Redundant and virtual constraints are checked from the edges list of the graph, ensuring accurate mobility calculation using the revised equation (Eq. (29)).

Furthermore, the dataset template automatically checks if all planetary gear sets are simple and determines the numbers of shifting couplings, brakes, and clutches. Additionally, the number of clutches containing the input link in the joint pair and its input clutch rate are evaluated. The spin losses are determined from the shifting couplings by counting the number of open actuators. Functionality evaluation involves analyzing the gear modes by calculating the total number of possible gear modes, the number of gear modes used as gear ratio, and the utilization rate of gear modes.

The gear specifications are automatically validated, with the number of gears being the only mandatory input functional data. If informed, the gear ratio values are considered to calculate the overall ratio spread, gear steps, and step deviation by comparing the PGM gear steps to an ideally progressive gear ratio progression (as discussed in [Section 2.1.1.1](#)) based on the first gear and the average step between gears. The count of underdrive gears, overdrive gears, and direct gears are also assessed. If the sequence of active shift couplings is provided, the calculated mobility through the revised equation is compared to the declared mobility, and the transition between gears is checked for single clutch-to-clutch shift transitions.

Ending validations, the dataset template checks all the verifications results for the minimum set of data compatible to be inserted into the dataset database.

The output of each PGM dataset template is a summarized list of feature values, which are later inserted into a centralized dataset control with all other PGMs analyzed. The results of this step are exemplified for the *US10563738B2__FIG_1* PGM in the following [Section 5.3.2](#).

5.2.4 Step 4. Raw Datasets

The datasets were created as spreadsheets in Google Sheets and stored in a Google Drive folder. Each spreadsheet is a source of the collected data which contains one or more related PGMs. Each worksheet in spreadsheet is a PGM dataset template representing a single mechanism.

A link to the Google Drive folder containing all datasets is available at [PGM Datasets folder](#).

5.3 PHASE 2: DATA ENRICHMENT - PGMS

In this section, the raw datasets of PGMs are enriched by the evaluation and inclusion of a diverse set of new features as shown below.

5.3.1 Step 1. Features Diversification

The features selected to diversify and attempt to uncover nontrivial information about PGMs are presented and integrated on [Table 20](#).

5.3.2 Step 2 and 3. Dictionary of Features and Data Evaluation

In these steps, the complete data dictionary of features ([Section 4.3.2](#)) is created by including the new features identified and selected in the [Section 5.3.1](#). A summary of the data associated with the PGMs' graphs was retrieved from a control spreadsheet on Google Drive. This data was then imported into the Google Colab ([BISONG, 2019](#)) environment, where SageMath ([DEVELOPERS, 2023](#)), used as the local computation backend associated to other libraries [Section 4.3.3](#), calculated the enriched data. An example of the results for the *US10563738B2__FIG_1* PGM is provided in [Table 20](#).

5.3.3 Step 4. Database

A comprehensive database has been developed to house the full set of features corresponding to each PGM. This database encompasses 160 PGM instances, each characterized by 186 features. Given the large amount of data, aiming to organize a more streamlined understanding of the thesis, each mechanism within the database is detailed in [Appendix A](#). This includes identification, topological, and functional data, along with the mechanism's functional diagram, and the PGM and DBG graphs. The distribution of data types in the database is depicted in the following [Figure 50](#).

Figure 50 – Distribution of data types in the database.

Source: Author.

The complete database can be found in the [PGM Complete Database Spreadsheet](#).

5.4 PHASE 3: FEATURE ANALYSIS - PGMS

The Feature Analysis phase was carried out in the environment mentioned in [Section 5.3.2](#). Subsequently, the processes of Data Preparation, Data Insights, Strategy Analysis, and Feature Selection were elaborated. These processes provided a comprehensive evaluation of the PGMs database leading to the identification of an optimal subset of features for the forthcoming gap discovery.

5.4.1 Step 1. Data Cleansing

During the Data cleansing step, the database, as referenced in [Section 5.3.3](#), was first verified for correct data types based on the feature dictionary detailed in [Section 5.3.2](#). Following this verification, thirteen features exhibiting constant values

were eliminated due to their lack of significance for the analysis. These features included *PGM LA n_7* , *PGM LA n_8* , *PGM LA n_9* , *PGM LA n_{10}* , *PGM LA n_{11}* , *PGM LA n_{12}* , *PGM__CL_count_simple__OUT*, *DBG Hollow Vertices (Nm)*, *DBG LA n_{11}* , *DBG LA n_{12}* , *Gears*, *DBG__Radius*, and *DBG__eccentricity_MJ*.

The investigation for missing values within the features was conducted, and the results can be found in Table 21. Features such as *Weight (kg)* and *Máx. Torque(N·m)* were excluded due to the absence of over 90% of their values. Missing values in other features, including *DATE*, *FWD Underdrive Gears*, *FWD Direct Drive Ratio*, and *FWD Overdrive Gears*, were replaced with the median value of their respective *FWD GEARS* group. This strategy was adopted to potentially extract valuable information in subsequent feature analyses.

Table 21 – Missing values in features.

Feature	Missing count	Missing %
<i>Weight (kg)</i>	151	94.38
<i>Máx. Torque (N·m)</i>	150	93.75
<i>RWD Máx. Ratio</i>	24	15.00
<i>FWD Underdrive Gears</i>	24	15.00
<i>FWD Direct Drive Ratio</i>	24	15.00
<i>FWD Overdrive Gears</i>	24	15.00
<i>FWD Overall Ratio</i>	24	15.00
<i>FWD Base ratio change (φ_1)</i>	24	15.00
<i>FWD Avg Progression Factor (φ_2)</i>	24	15.00
<i>FWD φ_2 STDEV</i>	24	15.00
<i>FWD φ_2 VAR COEF</i>	24	15.00
<i>FWD Reference diff</i>	24	15.00
<i>Direct drive?</i>	24	15.00
<i>PATENT</i>	15	9.38
<i>DATE</i>	9	5.62

Source: Author.

There were 24 PGMs (15% of total) with unspecified gear ratios, resulting in the absence of associated gear specifications. Estimation of these values was deemed unreliable; hence, the related eight features, including *RWD Máx. Ratio*, *FWD Overall Ratio*, *FWD Base ratio change (φ_1)*, *FWD Avg Progression Factor (φ_2)*, *FWD φ_2 STDEV*, *FWD φ_2 VAR COEF*, *FWD Reference diff*, and *Direct drive?*, were removed. Additionally, twelve obsolete metadata features, including *SOURCE*, *OWNER*, *PATENT*, *MODEL*, *CHECKLIST COMPLETE?*, *PGM_Edges*, *PGM_Nodes*, *DBG_Edges*, *DBG_Nodes*, *GEAR SPECS Check*, *Gear Ratios*, and *Gear Shiftings*, were also removed from the database.

A comprehensive comparison of all features was carried out to detect duplicates, i.e., identical column values. Five groups of duplicated features were identified, as listed:

1. **PGM Gear pairs** (j_G), **DBG Loops** (L_{DBG}), **DBG Gear pairs** (N_G), **DBG Dashed lines** (N_d)
2. **FWD GEARS**, PGM_Ca_1
3. **PGM Maximal degree** (ρ_{PGM}), **DBG maximal degree** (ρ_{DBG})
4. **DBG Number links** (N_l), **DBG Solid lines** (N_s)
5. **PGM Revolute pairs** (j_{Rb}), **DBG Planet links** (N_p), **DBG Revolute pairs 'b'** (N_{Rb})

Among the groups mentioned above, the five boldfaced features were retained, while the eight others were removed from the database.

A total of 43 features were removed from the database in the cleansing step, remaining 143 useful features.

Subsequent efforts were made to identify any duplicates in the database's instances (rows). Although no completely identical rows were discovered, a meticulous review for isomorphisms, especially regarding PGMs, was deemed essential. Four algorithms, namely VF2++, Weisfeiler Lehman (WL) Hash Test, Perimeter Loop, and Graph Edit Distance (GED), as mentioned in [Section 4.4.1](#), were employed for this purpose. Five sets, comprising a total of ten mechanisms, were identified as potential isomorphisms. A manual comparison of the PGM and DBG graph model representations confirmed their isomorphism. The sets of isomorphic PGMs, represented by their *UNIQUE_ID*, included:

1. **US6595892B2__FIG3**, US6595892B2__FIG9
2. **US6623398B2__FIG7**, US6623398B2__FIG9
3. **US6705967B2__FIG7**, US6705967B2__FIG9
4. **US6705967B2__FIG27**, US6705967B2__FIG31
5. **GM__AT_10_speed_L**, US8545362B1__AT_10_speed_L_10R80

It was noted that these isomorphic PGMs are often variants disclosed in patents, representing fundamentally the same mechanism. An instance of this observation was the collaboration between General Motors and Ford in developing a 10-speed AT, as cited in ([SCHIRMER, 2013](#); [GOLESKI; BALDWIN, 2013](#)). The five instances listed in boldface were retained in database, while the five others were removed.

After the database receive essential cleansing processes, it was made ready for further exploration. The cleansed database now comprises 155 PGM instances and 143 features, as depicted in [Figure 51](#).

The database containing all PGM data after cleansing ([Section 5.4.1](#)) is available in [PGM Prepared Database Spreadsheet](#).

Figure 51 – Distribution of data types in the database after the cleansing step.

Source: Author.

5.4.2 Step 2. Data Insights

An overview of the database is provided in Table 22. The 155 mechanisms (PGMs) are categorized based on the number of forward gears into five distinct groups. A total of 81 unique kinematic chains have been identified, differentiated by their respective DBG representation. A predominant portion of the PGMs has been designed for a longitudinal arrangement, with a single instance designed for dual usage. Out of the total, 20 PGMs have been identified as commercial products in the market. Structurally, the PGMs in database are composed of three, four, or five planetary gear sets (PGSs).

Table 22 – Database overview.

Forward Gears	PGMs	Unique DBGs	Arrangement			Commercial		No. of PGSs		
			Longitudinal	Transversal	Both	TRUE	FALSE	3	4	5
6	73	34	71	2	0	4	69	73	0	0
7	16	13	16	0	0	1	15	10	6	0
8	24	15	12	11	1	9	15	11	12	1
9	16	15	5	11	0	3	13	1	15	0
10	26	16	21	5	0	3	23	1	13	12
<i>Total</i>	<i>155</i>	<i>81</i>	<i>126</i>	<i>30</i>	<i>1</i>	<i>20</i>	<i>135</i>	<i>96</i>	<i>46</i>	<i>13</i>

Source: Author.

Given the large amount of space required for charts, aiming to organize a more streamlined understanding of the thesis, the visual analysis of features is provided in Appendix B. Charts are segmented by the number of forward gears (Appendix B.1.1), the total number of PGSs (Appendix B.1.2), and the commercial status (Appendix B.1.3). Following, the key insights of data analysis are detailed.

Univariate Analysis

A detailed visualization of the distribution for each feature, based on its data type, is presented in [Appendix B.1](#).

The dataset's feature distributions underwent statistical testing to check their normality ([Appendix B.1.4](#)). Besides visual inspections, the Shapiro-Wilk, D'Agostino's K^2 , and Anderson-Darling tests were applied, and only features that met all three test hypotheses were considered normally distributed. However, it was found that most features in the dataset did not follow Gaussian distributions. Notable exceptions included the betweenness centrality of the input link (denoted as *PGM__between__centrality_IN*) and the topological complexity of the mechanisms (designated as *PGM__Cx₃*). Both displayed Gaussian-like tendencies. Given these findings, nonparametric methods were primarily selected for subsequent statistical analyses to ensure an accurate representation and understanding of the data underlying patterns and distributions.

Bivariate Analysis

A detailed visualization of the correlation matrix is provided in [Appendix B.2](#), and the spreadsheet containing all correlations ([Section 5.4.2](#)) is available in [PGM Database Correlation Matrix Spreadsheet](#).

The correlation assessment between numerical features was conducted using Pearson's method when both features adhered to a normal distribution. Conversely, Spearman's method was utilized when at least one of the features deviated from a normal distribution. For the evaluation of categorical features, which encompass boolean data types, Cramér's V with bias correction was employed. In instances where the statistical significance (p-value) exceeded 0.05, the null hypothesis asserting no correlation between the feature pairs was accepted.

In this analysis, correlations were classified based on their absolute values, ensuring the classifications were valid for both positive and negative correlations. The correlation classes are specified in [Table 23](#).

Table 23 – Correlation classes for absolute values.

Class	Value Range	
	Low	High
Perfect	1	1
Very Strong	0.9	<1
Strong	0.7	<0.9
Moderate	0.5	<0.7
Weak	>0	<0.5
None	0	0

Source: Author.

In the database investigation, a total of 10,153 unique correlation pairs were analyzed. Among these, 13 pairs exhibited perfect correlations, and 170 showcased very high correlations, jointly accounting for 1.8% of the database. On the contrary, 4,464 pairs displayed weak correlations, and 3,275 pairs revealed no correlation, together making up 76.2% of the entire dataset. A thorough representation of the correlation strengths is provided in Figure 52.

Figure 52 – Distribution of the correlation pairs by strength in database.

Source: Author.

Based on the analysis of the perfect correlations, nine groups comprising 20 unique features were identified, as enumerated below:

- *PGM Gear pairs (j_G), PGM Maximal degree (p_{PGM})*
- *DBG Number links (N_l), DBG VERTICES (v), DBG Revolute pairs (N_R)*
- *DBG Link Assortment (LA), DBG CLASS*
- *DBG__STD_Degree, DBG__Variance_Degree*
- *DBG__degree_centrality_MJ, DBG__close_centrality_MJ*
- *DBG Coaxial links (N_c), DBG Revolute pairs 'a' (N_{Ra})*
- *PGM DOFs, PGM__Ca₂, Active SCs per gear*
- *PGM__CL_size_F, PGM__CL_count_single_F*

Within these groups, three features presented perfect negative correlations in their respective groups: *PGM__Ca₂*, *PGM__CL_size_F*, and *PGM__CL_count_single_F*.

5.4.3 Step 3. Strategic Analysis

This step presents strategic analyses for both local and global features within PGMs. For the local features, a link analysis focuses on the characterization of frame (F), input (IN), and output (OUT) with respect to compound links and their adjacency. For the global features, three strategic analyses are conducted: sequence arrangement

of PGSs within each PGM, structural complexity of PGMs, and technological boundary map for PGMs.

These analyses provide insights into the local and global characteristics of PGMs in database, enabling a comprehensive understanding of its structure and functionality.

5.4.3.1 Links Analysis

The frame (F), input (IN), and output (OUT) links were analyzed to determine their compound compositions, adjacency connections, and centrality measures. The results were segmented by three primary characteristics: the number of forward gears, the total count of PGSs, and the commercial status. Due to space limitations, graphical representations of these results for each link are provided in [Appendix B.3](#), and serve as a source of consultation for specific designs for each segment. The overall results are discussed below.

Frame (F) link

In the frame (F) link composition analysis, it is predominantly a single (not compound) link, accounting for 52.9% of the 155 instances. The remaining are compounds with only one elementary link of which 32.3% is a sun (S), 8.4% is an arm (A), and 6.5% is a ring (R).

The adjacency analysis conducted on the Frame (F), it was found that the link frequently exhibited an adjacency degree of 5 (33.5%), an eccentricity of 3 (62.6%), and was associated with 2 brakes (34.8%). On average, the adjacent elementary links composition is 27.9% S, 33.0% A, 30.5% R, and 8.6% P, being the combination of 'S:2,A:3,R:1,P:0' as the most prevalent, representing 6.5% of the instances. On average, the adjacent joints composition is 45.1% j_{R_a} , 2.6% j_{R_b} , 9.0% j_G , and 43.3% B , being the combination of ' $j_{R_a}:2, j_{R_b}:0, j_G:0, B:3$ ' as the most prevalent, representing 20.6% of the instances.

Input (IN) link

In the composition analysis of the Input (IN) link, compounds predominantly contain one elementary link, representing 80.0% of the instances. Within this category, 31.0% are identified as an arm (A), 29.7% as a sun (S), and 19.4% as a ring (R). Other compositions include 14.3% with two elementary links, 5.2% with a single link, and solely 0.6% with three elementary links.

The adjacency analysis conducted on the Input (IN), it was found that the link frequently exhibited an adjacency degree of 3 (49.0%), an eccentricity of 3 (71.6%), and was associated with 1 clutches (73.5%). On average, the adjacent elementary links composition is 25.2% S, 27.1% A, 16.8% R, and 30.9% P, being the combination of

'S:1,A:2,R:0,P:1' as the most prevalent, representing 8.4% of the instances. On average, the adjacent joints composition is 27.8% j_{R_a} , 13.4% j_{R_b} , 19.5% j_G , and 39.2% C , being the combination of ' $j_{R_a}:1, j_{R_b}:0, j_G:1, C:1$ ' as the most prevalent, representing 27.7% of the instances.

Output (OUT) link

In the composition analysis of the Output (OUT) link, compounds predominantly contain one elementary link, representing 61.9% of the instances. Within this category, 34.8% are identified as a ring (R), 21.9% as an arm (A), and 5.2% as a sun (S). Other compositions include 35.5% with two elementary links, solely 2.6% with three elementary links, and no single link.

The adjacency analysis conducted on the Output (OUT), it was found that the link frequently exhibited an adjacency degree of 2 (46.5%), an eccentricity of 3 (80.6%), and was associated with Longitudinal arrangements (80.6%). On average, the adjacent elementary links composition is 16.9% S, 13.0% A, 12.8% R, and 57.3% P, being the combination of 'S:0,A:0,R:0,P:1' as the most prevalent, representing 25.2% of the instances. On average, the adjacent joints composition is 37.4% j_{R_a} , 22.0% j_{R_b} , 25.4% j_G , and 15.2% C , being the combination of ' $j_{R_a}:1, j_{R_b}:0, j_G:1, C:0$ ' as the most prevalent, representing 35.5% of the instances.

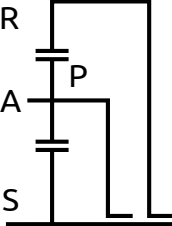

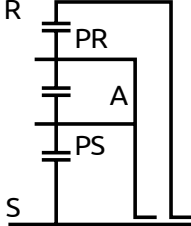

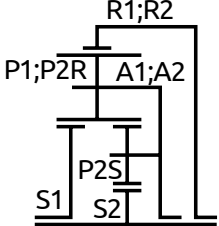

5.4.3.2 PGSs Sequence Arrangement Analysis

This strategic analysis examines the sequence in which PGSs are arranged and interconnected within the overall PGM structure. Three fundamental PGS types, defined in Table 24, are considered to compose a PGM: Simple PGS (S), Double PGS (D), and Ravigneaux PGS (R) which is a composition of Simple and Double elementary PGSs.

The arrangement of PGSs in sequence was determined based on the PGM diagrams in Appendix A.2. The PGS connected to the input (IN) link was identified as PGS number 1, with subsequent PGSs enumerated towards the opposite side of the transmission. The arrangement orders, essential for this structural analysis, are represented as PGSs sequences enclosed in brackets, with the input PGS positioned leftmost, followed by the remaining PGSs.

Table 25 presents 15 unique PGSs sequence arrangements identified in the database, segmented by commercial status ('TRUE'), total count of elementary PGSs (3 to 5), and number of forward speeds (6 to 10). The sequence with three Simple PGSs is the most prevalent, found in 63 PGMs, of which 53 represent mechanisms with six forward speeds, 7 with seven, and 3 with eight (only one being commercial). The

Table 24 – Fundamental PGS types in sequence arrangements.

Features	Simple (S)	Double (D)	Ravigneaux (R)
Diagram			
PGS Count	1	1	2
Links (n)	4	5	6
Planet links (n_p)	1	2	2
Coaxial links (n_c)	3	3	4
Compound Links (CL)	0	0	3
Joints (j)	5	7	9
Gear joints (j_G)	2	3	4
Revolute joints (j_R)	4	5	6

Revolute joints 'b' (j_{Rb})	1	2	2
Mobility (DOF)	1	1	1

Source: Author.

sequence with four simple PGSs is the second most common (33 PGMs), with mechanisms generating between seven and ten forward speeds (being ten commercial).

This analysis also highlights the diversity of PGMs showing variations in the sequence arrangements for the same PGS type compositions. For instance, in the case of sequences with two simple and one double PGSs, there are eight [S,S,D], three [S,D,S], and five [D,S,S] sequences.

In the subsequent [Section 5.5](#), PGSs sequences are analyzed to identify potential innovation gaps.

5.4.3.3 Complexity Analysis

This study compares the structural complexity metric ' PGM_Cx ' presented in [Section 3.2.1](#) with other metrics potentially related to the complexity of PGMs. The goal is to identify the metric that best distinguishes and represents the complexity of different mechanisms. For this purpose, the individual terms of ' PGM_Cx ', namely component ' PGM_Cx_1 ', interface ' PGM_Cx_2 ', and topological ' PGM_Cx_3 ', were considered. Additionally, metrics as the number of independent loops ' PGM Loops (L_{PGM})', the aggregate of shift couplings and gear pairs termed ' PGM Complexity Karhula', and the network complexity coefficient ' $PGM_Complexity_Coeff$ ' ([Section 4.3.1.2](#)) were evaluated. A statistical overview of these complexity features is provided in [Table 26](#).

The analysis of [Table 26](#) reveals that ' PGM_Cx ' exhibits the highest number of unique values (143) and spans a broad range (270.592 to 553.213). This suggests

Table 25: PGSs sequences in the database.

PGSs Sequence *	Commercial?	PGSs Total			FWD GEARS

Source: Author.

its potential for providing fine-grained distinctions between mechanisms, even among isomorphic ones. Furthermore, its constituent terms offer insights into various facets of structural complexity.

The link complexity term ' PGM_Cx_1 ' possesses 123 unique values, with a mode of 69.889 observed in 49 PGMs. This observation implies that groups of mechanisms may share similar link characteristics, possibly due to common patent origins. The coupling complexity ' PGM_Cx_2 ' distinguishes 143 unique values, the same granularity of the structural complexity, while the topological complexity ' PGM_Cx_3 ' demonstrates lower sensitivity (124 unique values) in differentiating PGM complexity.

Among other complexity-related metrics, the network complexity coefficient ' $PGM_Complexity_Coeff$ ' stands out with 46 unique values. Both ' $PGM_Loops (L_{PGM})$ ' and ' $PGM_Complexity_Karhula$ ' identify only 6 distinct mechanism groups, demonstrat-

ing their limited ability to capture the nuances of PGM complexity. These shortcomings likely stem from their limitation to consider the interaction between compound links, joint characteristics, and overall kinematic structure.

Several other metrics within the database exhibit a high number of unique values. However, these metrics focus on local link-specific features (F, IN, OUT). Examples include centrality metrics like '*PGM__katz_centrality_IN*' (135 unique values), '*PGM__katz_centrality_OUT*' (134 unique values), and others as detailed in [Appendix B.3](#).

Furthermore, a correlation analysis was conducted to examine relationships between complexity metrics. [Figure 53](#) presents the results as a heatmap.

Figure 53 – Correlation heatmap of PGM Complexity metrics.

Source: Author.

The structural complexity metric '*PGM__Cx*' exhibits strong positive correlations with multiple features and no observed negative correlations. Specific findings include:

- Structural Complexity '*PGM__Cx*':
 - A very strong positive correlation with its interface component '*PGM__Cx₂*', suggesting a potential linear relationship.
 - A very strong positive correlation with the number of independent loops '*PGM Loops (L_{PGM})*', reinforcing its relationship with the interface component '*PGM__Cx₂*'.
- Link Complexity '*PGM__Cx₁*':
 - A very strong positive correlation with '*PGM Complexity Karhula*', indicating that the latter metric may be primarily influenced by link complexity.
- Topological Complexity '*PGM__Cx₃*':
 - Demonstrates weak to non-significant correlations with other metrics, em-

phasizing its unique ability to capture distinct aspects of complexity of the topology.

- Network Complexity Coefficient '*PGM__Complexity_Coeff*':
 - Exhibits strong positive correlation with '*PGM__Avg_Degree*', meaning it is mostly an average metric of the graph.

Table 27 presents four similar planetary gear mechanisms arranged in order of increasing structural complexity. Information in the table highlights their distinct characteristics and use complexity metrics (indicated in gray) to quantify these differences. Despite sharing several features, subtle variations in their configurations result in increasing complexity. All four PGMs exhibit the following commonalities: longitudinal arrangement, six forward (FWD) and one reverse (RWD) speeds, three planetary gear sets (PGSs), five shifting couplings (SCs), one input clutch, and seven revolute pairs at level 'a'. Furthermore, they have compound links for frame (F), input (IN), and output (OUT), each composed with a single elementary link.

The comparative analysis of the four PGMs reveals the following insights:

- PGM *US6530858B1__FIG25* exhibits the highest complexity due to:
 - a combination of one double PGS and two simple PGSs (versus three simple PGSs in others)
 - one brake and four clutches (versus only clutches in others)
 - 12 links (highest in the comparison)
 - 18 joints (two more than others)
 - 7 gear pairs (one more than others)
 - 4 revolute pairs in level 'b' (one more than others)
 - a link partition with 2 binary, 8 ternary, and 2 quaternary links
 - a non-planar graph
- PGMs *US6514170B1__FIG4* and *US6595892B2__FIG1* are similar in most aspects. However, *US6595892B2__FIG1* is considered more complex due to:
 - an additional joint in the input (IN) link, indicating increased coupling complexity
 - this complexity exists despite having a planar graph
- PGM *US6530858B1__FIG23* exhibits the lowest complexity, primarily due to:
 - a higher proportion of binary links and fewer ternary links in its partition compared to the others.

An analysis of complexity metrics indicates that the number of loops (L) and the Karhula complexity metric provide limited insight into the complexity differences among these PGMs. While the network complexity coefficient successfully identifies the least

Source: Author.

complex mechanism, it rates both *US6514170B1__FIG4* and *US6595892B2__FIG1* as highly complex. This coefficient demonstrates strong correlations with link assortments (0.947) and average degree of adjacency (0.937). However, these network features offer limited characterization of specific link and joint types within PGMs.

A detailed examination of the structural complexity metric '*PGM__Cx*' and its components reveals the following:

- Link Complexity '*PGM__Cx₁*':
 - This metric offers limited differentiation among the first three PGMs. Despite an additional link in *US6530858B1__FIG23*, its lower average degree of adjacency contributes to its perceived similarity. Notably, the highest link complexity is exhibited by *US6530858B1__FIG25* due to its 12 links.
- Coupling Complexity '*PGM__Cx₂*':
 - This metric effectively distinguishes joints complexity among the PGMs, accurately capturing local link-specific features (F, IN, OUT), even when PGMs share similar joint counts.
- Topological Complexity '*PGM__Cx₃*':
 - This metric indicates that all PGM topologies are hierarchical (as defined in [Section 3.2.1.3](#)). Their partitions support this finding, with each PGM possessing two quaternary links, several ternary links, and few binary links. *US6595892B2__FIG1*, being the unique planar graph, is identified as having the least complex topology. *US6530858B1__FIG23* exhibits a more complex topology than *US6514170B1__FIG4* due to having more links for an equivalent number of joints. As expected, *US6530858B1__FIG25* has the most complex topology, aligning with findings from [Table 27](#).
- Overall Structural Complexity '*PGM__Cx*':
 - Despite limitations in its '*PGM__Cx₁*' component, this metric provides the most accurate and comprehensive assessment of PGM complexity when compared to the previously discussed metrics.

5.4.3.4 Technological Boundary Map for PGMs

This section introduces an updated technological boundary map for PGMs, inspired by the model presented in [Figure 28](#). The updated map utilizes PGM Structural Complexity ('*PGM__Cx*') on the x-axis and PGM Capability ('*PGM__Ca*') on the y-axis. This new representation offers a more precise view of each mechanism, as illustrated in [Figure 54](#).

Analysis of the chart reveals that PGMs positioned further to the left on the x-axis exhibit lower complexity. The integer values of capability on the y-axis correspond

Figure 54 – Technological Boundary Map for PGMs.

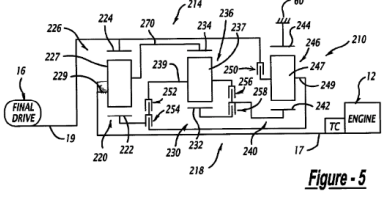

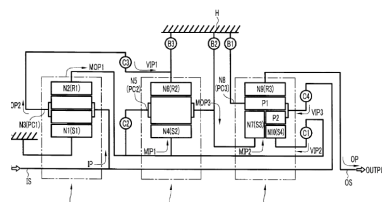

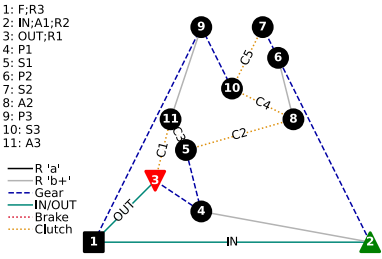

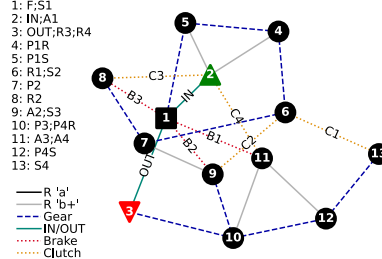

to the number of forward speeds, with higher positions indicating greater capability. Additionally, within the interval between two integer capability values, a higher position of a PGM suggests less mobility needed to achieve that specific number of forward speeds. As well as, the mechanisms are segmented by the number of speeds (represented by different colors) and by their commercial status (symbolized by 'o' for FALSE and '*' for TRUE).

Table 28 presents the two PGMs that represent the extremes of the technological map (Fig. 54) in terms of the structural complexity. These PGMs represent the simplest and the most structurally complex mechanisms identified in the analysis.

5.4.4 Step 4. Feature Selection

This study implemented a multi-faceted approach to evaluate and select the most relevant features for PGM design. The analysis focused on three main characteristics:

Table 28: Comparison of the least and most complex PGMs in database.

Source: Author.

the commercial status of the PGMs, the count of PGSSs, and the number of forward gears.

A comprehensive Python function was developed for this purpose, encompassing data preparation, splitting and preprocessing, evaluation of feature importance, and aggregation of feature rankings from various methods.

Initially, the data was processed to address missing values in both numerical and categorical features. Subsequently, it was divided into predictor variables and a target variable. The following features were selected as target variables:

- For the commercial status '*Commercial?*':
 - the PGMs with a status of "TRUE".
- For the planetary gear sets:
 - total count of PGSSs.
- For forward speeds '*FWD GEARS*':
 - each forward gear in the range from 6 to 10 speeds.

A *Column Transformer* was utilized to standardize numerical features and *One-Hot Encoding* was applied to categorical features.

The evaluation of feature importance was conducted through a series of methods. A *Random Forest Classifier* was trained to determine feature importance. Additionally, *Recursive Feature Elimination (RFE)* with a *Logistic Regression* estimator was used to identify the top features. Univariate statistical methods, such as *F-scores* for numerical features and *Chi-squared scores* for categorical features, provided further insights. *L1 Regularization* using *LassoCV* also contributed to the feature selection process by highlighting the most significant features.

A two-step approach was employed to identify the most relevant features for each target variable. In the first step, feature rankings were aggregated using *weighted rank aggregation* and *mean rank computation*. This was followed by *score normalization* to ensure all features were on a comparable scale and contribute equally to the final ranking. The *weighted rank* was chosen as the primary metric for this analysis, and the top 15 most relevant features for each target variable are presented in [Table 29](#), listed by order of importance.

These results may provide a valuable reference for prioritizing essential features in the design process.

Visual representations of the top features identified through all six methods for each target are delineated in [Appendix B.4](#), providing a clear and comprehensive detailing of the results.

5.5 PHASE 4: GAP DISCOVERY - PGMS

5.5.1 Step 1. Gap Search

The gap discovery step investigated features in both global and local contexts to identify ranges of missing values based on the database segmentation.

Analyzing the **global context**, which encompasses features from the entire PGM database, 46 features were identified as containing gaps, suggesting potential opportunities for innovation. Notably, PGS sequence arrangements is the only feature related to property type of the structural scope that exhibited gaps.

The analysis of PGSs sequence arrangements in [Section 5.4.3.2](#) revealed potential innovation gaps due to their role as a global structural property of PGMs. All possible combinations of fundamental PGS types were generated covering the range of gear pairs (j_G) (6 to 10) and total number of elementary PGSs (3 to 5) present in the database (details on these fundamental PGS types are provided in [Table 24](#)). Disregarding the exclusion of PGS links during PGT construction, a total of 44 sequence arrangements were identified, distributed across 16 possible combinations of fundamental PGS types. By analyzing these arrangements for gaps, 24 sequence arrangements

were identified as missing entries (gaps) in the database, distributed across 8 combinations of fundamental PGS types. Details on these gaps in sequence arrangements for global context are presented in [Table 30](#).

Table 30: Identified gaps in PGSs sequence arrangements for global context.

Source: Author.

Of the remaining 45 features with gaps identified in the global context, 40 are structural metrics, and the remaining 5 are functional metrics. These gaps in features representing metrics requirements can be valuable for decision-making in subsequent stages once kinematic chain structures have been generated.

Analyzing the **local context**, the search for gaps focused on three principal characteristics: the commercial status of the PGMs, the total count of **PGSs**, and the number of forward speeds.

The analysis of PGMs segmented by **commercial status "TRUE"** identified 52 features containing gaps, suggesting potential opportunities for innovation. The most significant gaps were observed in six requisite properties, which are detailed in [Table 31](#). The remaining gaps were identified in 41 structural metrics and 5 functional metrics.

The analysis of PGMs segmented by **total count of 3, 4, and 5 elementary PGSs** is summarized below.

An examination of PGMs with a *total count of 3 elementary PGSs* revealed 48 features containing gaps, suggesting potential for innovation. The most significant gaps were observed in two requisite properties, detailed in [Table 32](#). The remaining gaps were identified in 41 structural metrics and 5 functional metrics.

Similarly, for PGMs with a *total count of 4 elementary PGSs*, 48 features containing gaps were identified, indicating potential innovation opportunities. The most significant gaps resided in two requisite properties, presented in [Table 33](#). The remaining gaps were found in 41 structural metrics and 5 functional metrics.

Finally, the analysis of PGMs with a *total count of 5 elementary PGSs* identified 50 features containing gaps, suggesting potential for innovation. In this segment, the most significant gaps were observed in six requisite properties, detailed in [Table 34](#). The remaining gaps were identified in 39 structural metrics and 5 functional metrics.

5.5.2 Step 2. Gap Analysis

This section focuses on analyzing and prioritizing gaps in features based on their innovation potential for PGM topology. A prioritization scheme is established, detailed in Table 40, which ranks criteria in descending order of importance.

The *Topology and Performance ranks* criteria consider the correlation values between features and the position of gap values according to optimization goals. The feature correlations are evaluated to three strategic metrics relevant to structural complexity and capability of the mechanisms:

- 'DBG__Cx': Kinematic chain structural complexity. Goal: ↓ *minimize*.
- 'PGM__Cx': Mechanism structural complexity. Goal: ↓ *minimize*.
- 'PGM__Ca': Mechanism capability. Goal: ↑ *maximize*.

Considering only numeric features, the *Gap Correlation Index* for each metric is calculated using the general formula (Eq. (47)):

$$\text{Gap Correlation Index} = \text{Normalized Gap Value} \cdot (|\text{Correlation Value}|)^{\text{Weighting Factor}}, \quad (47)$$

where:

- *Normalized Gap Value* represents the position of a gap within the valid range of its corresponding feature in the local context. This value is calculated to account for both individual and range-based gaps. It is determined as follows:

Table 40: Prioritization scheme for feature gaps by innovation potential.

Rank	Criteria	Ordered Values
1	Database Context <i>Feature gaps in global contexts are prioritized over those in local contexts. The risk of representing infeasible solutions must be evaluated by the designer.</i>	global local
2	Requisite Scope and Type <i>Gaps in features of the structural scope (particularly those related to property requirements) receive the highest priority as they represent potential innovation in PGM structural synthesis. Features of the functional and technical scopes (particularly those related to property and metric requirements) are more relevant to dimensional synthesis.</i>	structural property structural metric functional property functional metric technical property technical metric
3	Machine Scope <i>Gaps in features associated with the kinematic chain (PGT), represented by <i>DBG</i> graph features, are considered more innovative. This prioritizes gaps in features related to the core topology of the mechanisms, as PGMs are built upon kinematic chains.</i>	PGT PGM AT link joint
4	Topology <i>Gaps with a strong correlation to reducing PGM structural complexity are considered to have more innovation potential.</i>	
5	Performance <i>Gaps with a strong correlation to enhancing PGM capability are considered to have more innovation potential.</i>	
6	Feature Relevance <i>Gaps are ordered by the most relevant features for each context.</i>	Table 29
7	Frequency <i>Gaps that appear most frequently across multiple local context analyses are considered more significant.</i>	

Source: Author.

- For features where higher values are desirable (e.g., '*PGM__Ca*'):

$$\text{Normalized Gap Value}_{\uparrow\text{maximize}} = \frac{\text{Max Gap Value} - \text{Feature Lower Bound}}{\text{Feature Upper Bound} - \text{Feature Lower Bound}}$$

- For features where lower values are desirable (e.g., '*DBG__Cx*', '*PGM__Cx*'):

$$\text{Normalized Gap Value}_{\downarrow\text{minimize}} = \frac{\text{Feature Upper Bound} - \text{Min Gap Value}}{\text{Feature Upper Bound} - \text{Feature Lower Bound}}$$

- *Correlation Value* represents the correlation coefficient between the feature with a gap and the corresponding strategic feature, as determined in [Section 5.4.2](#). Weak correlations (< |0.5|) are disregarded.
- *Weighting Factor* emphasizes the importance of correlation value in this ranking. An empirical value of 1.5 was used in this case.

Therefore, features with stronger correlations (positive or negative depending on the optimization direction) to the strategic features receive higher correlation ranks.

The *Feature Relevance rank* is based on the features relative importance within their local context. The *Relevance Index* is the inverse of the ranking resulted from the feature selection process (Tab. 29) and is calculated as follows (Eq. (48)):

$$\text{Relevance Index} = \frac{1}{\text{Feature Rank}_{\text{Local Context}}} . \quad (48)$$

Otherwise, the relevance index for features not present in the local context is 0. Thus, a higher relevance index indicates a significantly greater potential for innovation within that context.

Following the established prioritization scheme (Tab. 40), the gaps in property requisite features were ranked based on stronger correlations to strategic metrics in the desired optimization direction, higher relevance, and higher frequency across contexts. The resulting rank, detailed in Table 41, identifies gaps in features with the highest potential for innovation in PGMs.

Table 41: Innovation potential rank of gaps in property requisite features.

The analysis revealed 27 potentially innovative gaps within 12 distinct property features across 9 local contexts. For structural requirements related to kinematic chains (PGTs), the gap with the highest potential for innovation is 21 joints in the DBG graph for transmissions with 10 forward speeds. For entire mechanisms (PGMs), the gap with the most significant potential for innovation is 20 joints in the PGM graph for transmissions with 5 elementary PGSs. When analyzing the gaps associated with functional properties, PGMs with 9 forward speeds and 5 elementary PGSs exhibit the most noteworthy potential for innovation. Further analysis in the following sections details the remaining potentially innovative gaps.

5.5.3 Step 3. Gap Clustering

Gaps in PGSs sequence arrangements were clustered with structural and functional property features gaps within specific local contexts (Tab. 41). Nine potential clusters for innovation were identified across various contexts, as detailed in Table 42, utilizing the feature gap prioritization scheme (Tab. 40). These clusters are presented in descending order of priority. Forward gear configurations ranging from six to ten speeds, particularly ten-speed configurations, demonstrate significant potential for innovation. Additionally, all planetary gear set (PGS) configurations offer development opportunities, with five-PGS transmissions exhibiting notable potential for innovation in mechanisms with nine gears.

5.5.4 Step 4. Innovation Sets

Innovation sets for each local context were generated by combining PGT features gaps based on the clusters identified in [Table 42](#). The feasibility of each PGSs sequence arrangement was evaluated for every feature combination to ensure the practicality and potential utility of the proposed innovation sets. The corresponding local context PGM features and gaps were integrated to complete each innovation set. This process resulted in at least 13 innovation sets of feasible combinations organized and prioritized based on their innovation potential, as presented in [Table 43](#).

Table 43: Innovation Sets within local contexts.

Source: Author.

These sets may be further combined based on additional criteria, as determined by the designer's expertise and the study's objectives. The innovation sets represent promising requisites for the development of novel PGMs, effectively addressing identified gaps focused on the potential of each context.

Using these innovation sets as design requirements for new PGMs substantially reduces the design space. This reduction, facilitated by the identified attribute gaps, can guide the generation of alternative mechanism solutions. Consequently, this approach streamlines the design process, optimizing time and resources while promoting innovative solutions without the need for an exhaustive search.

6 PGMS DESIGN USING INNOVATION SETS

This chapter demonstrates how innovation sets identified in [Chapter 5](#) are used to design potentially novel Planetary Gear Mechanisms (PGMs). The following section will detail the PGM synthesis process by presenting a discussion of initial concept generation and then progressing to an examination of the proposed diagrams for the two potentially new PGM configurations.

6.1 SYNTHESIS PROCESS

The first innovation set in [Table 43](#) was chosen to exemplify the synthesis process of potential novel PGMs. This specific innovation set was identified for the local context of 10 forward speeds and presents four features with clearly defined gaps, as follows:

- DBG LA $n_3 = 9$
- DBG JOINTS (e) = 21
- PGM LA $n_3 = 9$
- PGSs Sequences = [S,S,S,D], [S,S,D,S], [S,D,S,S], [S,S,D,D], [S,D,D,S], [S,D,S,D], [S,S,S,R], [S,S,R,S], [S,R,S,S], [D,S,S,S], [D,S,D,S], [D,D,S,S], [D,S,S,D], [R,S,S,S], [S,D,R], [S,R,D], [S,R,R], [D,D,D], [D,D,R], [D,R,D], [D,R,S], [R,D,S], [R,D,D], [R,R,S], [R,S,R].

This implies that PGMs with 10 forward speeds and exhibiting any of these specific feature values are absent from the existing database. Given the context, the desired number of gears will be $m_r = 11$, consisting of ten forward speeds and one reverse speed.

To characterize the context of ten-speed transmissions, key features, their respective values, and correlations with PGT complexity and PGM capability were identified through analysis of the 26 mechanisms in the database. These are highlighted below in [Table 44](#).

The PGSs sequence $1S+1D+1R$ [S,R,D], shown in [Figure 55](#), was selected as a reference for the synthesis of potentially novel PGMs. This selection was motivated by two key factors. First, the chosen sequence possesses a more compact and less complex structure compared to the other alternative sequences. Second, the sum of the joints in the kinematic chain is $e = 21$, which aligns with the target number of joints desired for the innovation set.

To form the kinematic chain, all possible compound links between the coaxial links of the PGSs were generated, totaling 7881 PGTs represented by DBG graphs. However, an analysis of degeneration (rigid sub-chains) led to the removal of almost half of the PGTs, resulting in 4086 non-degenerated kinematic chains. Isomorphism evaluation further eliminated a significant number of candidate solutions, ultimately

Table 44: Characterization of 10 forward speed local context.

Table 45: Top 10 new potential PGTs. (Continued)

Source: Author.

An initial investigation into the Table 45 identified the PGT $1S+1D+1R_{277}$ as a promising candidate for the development of a new PGMs. This selection was motivated by two key factors. First, PGT $1S+1D+1R_{277}$ exhibits the lowest structural complexity metric among all entries within the table, with a DBG complexity value (DBG C_x) of 325.67. Second, this PGT possesses nine ternary links in its kinematic chain. The schematic diagram of the PGT $1S+1D+1R_{277}$ is presented in Figure 56 for further visualization.

Figure 56 – Schematic diagram of the PGT $1S+1D+1R_{277}$.

Source: Author.

The next step involved determining the Frame (F), Input (IN), and Output (OUT) links. Database strategic link analysis (Section 5.4.3.1) for the context of PGMs with four total PGSs revealed a prevalence of single links used as Frames (Fig. 353). Input (IN) links were most frequently identified as compound links joined to a single elementary link, typically the sun gear (S) Fig. 358). Similarly, Output (OUT) links were consistently

observed to be compound links formed by one or two elementary links, with the arm link (A) being the most common (Fig. 363).

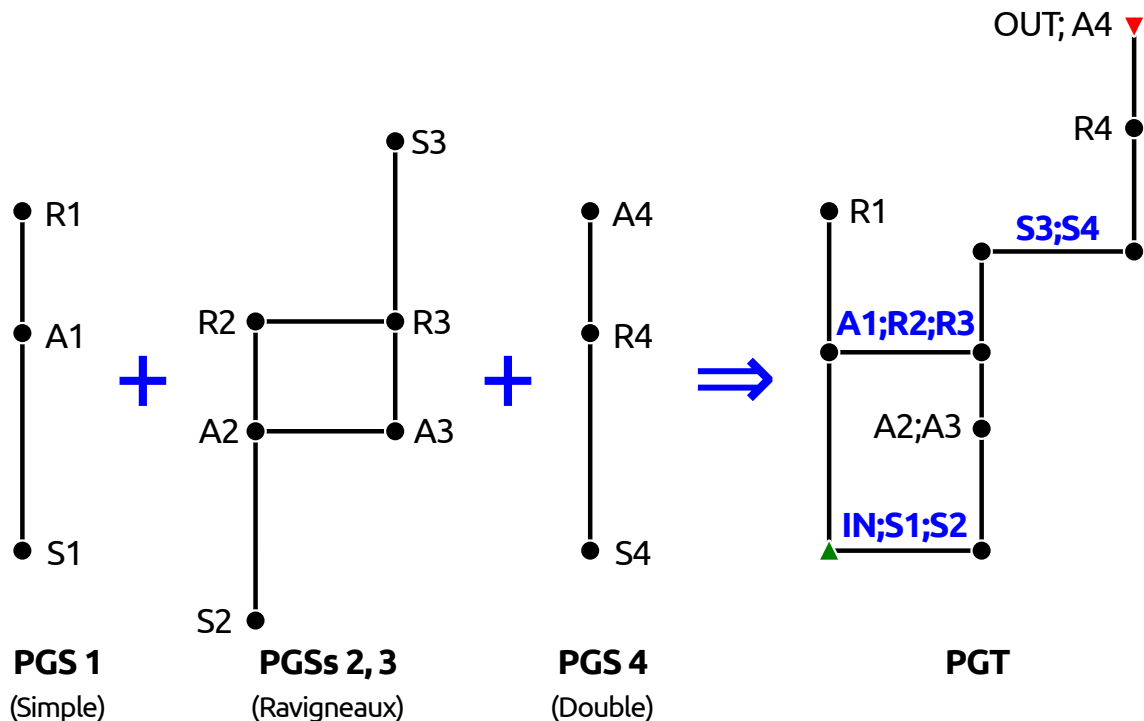

Based on these findings, the following links were selected for the construction of the PGM:

- Frame (F): Single link.
- Input (IN): Compound link associated with the sun gear of PGS 1 (IN;S1).
- Output (OUT): Compound link associated with the arm of PGS 4 (OUT;A4).

The PGT $1S+1D+1R_{277}$ is composed of $n = 13$ links and $j = 21$ joints ($j_G = 9$ gear pairs, $j_{Ra} = 7$ revolute pairs in level 'a', and $j_{Rb+} = 5$ revolute pairs in level 'b+'). Applying Equation (29), this initial configuration results in a mechanism with 3 degrees of freedom (DOF).

A preliminary kinematic analysis of the PGM's gear modes (Eq. (14)) was performed. The lever analogy method (BENFORD; LEISING, 1981; DING et al., 2020; YANG et al., 2022) was employed to identify the necessary shift couplings (SC) as brakes (B) and clutches (C). Each elementary PGS within the PGT $1S+1D+1R_{277}$ is represented by a lever. These levers are interconnected through the compound links (Fig. 57), facilitating the evaluation of all possible gear modes.

Figure 57 – Lever diagram of the PGT $1S+1D+1R_{277}$.

Source: Author.

The Simple PGS (1) connects directly to the Ravigneaux PGS (2 and 3) through two compound links: (IN;S1;S2) and (A1;R2;R3). This configuration restricts the internal mobility of the Simple PGS. Conversely, the Double PGS (4) has only one direct

connection to the Ravigneaux PGS, the compound link (S2;S3). Consequently, shift couplings should prioritize connections to PGS 4 to reduce its internal mobility to one.

Considering the PGM's 3-DOF configuration, each pair of shift couplings represents a potential gear mode. Five of the seven coaxial links have the potential to serve as brakes when connected to the housing (F). Four of these are selected, excluding the input (IN;S1;S2) and output (OUT;A4) links, which cannot be constrained, and the arm (A2;A3) to avoid blocking potential clutches.

Initial analysis identified 21 pairs of coaxial links as potential clutches. However, 10 of these pairs would result in atresia, a condition where all links within a PGS rotate as a single unit (DING et al., 2020), and are therefore discarded. Further analysis of the remaining 11 pairs within the schematic diagram (Fig. 56) reveals that 8 pairs are either infeasible or can be eliminated. The pair (IN;S1;S2, R4) is considered inaccessible. Four pairs containing link 'R1' are discarded to prevent blocking of potential brakes and clutches and to prioritize connections with PGS 4. Two pairs would lock the mechanism: (R1;S3;S4) and (IN;S1;S2, S3;S4). The pair (IN;S1;S2, OUT;A4) represents a direct input-output connection. This leaves 3 clutches and 4 brakes for potentially further evaluation, as shown in Figure 58 and listed below:

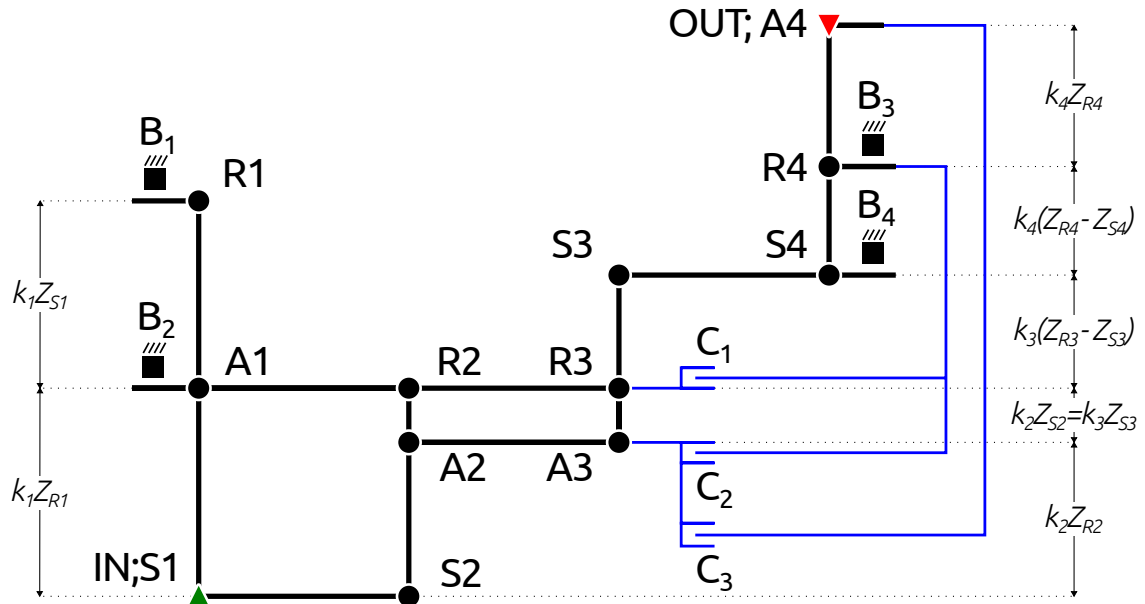

- Clutches
 - C_1 : (A1;R2;R3, R4)
 - C_2 : (A2;A3, R4)
 - C_3 : (A2;A3, OUT;A4)
- Brakes
 - B_1 : (F, R1)
 - B_2 : (F, A1;R2;R3)
 - B_3 : (F, R4)
 - B_4^* : (F, S3;S4)

* Note: the access of the link (S3;S4) to the housing (F) only occurs when the output is transversal, i. e., the link (OUT;A4) is a gear connecting another gear in an external parallel axis.

Of the six possible brake pair combinations, three contain links from the same PGS, resulting in a locked mechanism. Additionally, the pair (B_1, B_4) would not transmit rotation to the fourth PGS. These combinations are discarded, leaving only two viable brake pairs: (B_1, B_3), and (B_2, B_3).

The total number of potential gear modes is determined by the feasible brake pairs, the combination of a brake and a clutch, and three direct modes achievable by engaging any pair of clutches (Eq. (49)):

$$\text{Potential Gear Modes} = 2 + 4 \times 3 + 3 = 17. \quad (49)$$

Figure 58 – Lever diagram of the PGT $1S+1D+1R$ _277 with potential shift couplings.

Source: Author.

A preliminary kinematic analysis using the lever method geometrically identified all possible gear modes as shown in Table 46.

Table 46: Summary of preliminary gear modes for PGM $1S+1D+1R$ _277.

Shift Couplings	B_1	B_2	B_3	B_4	C_1	C_2	C_3
B_1		X	R	X	U	O	U
B_2			U [†]	X	U [†]	O	U

C_2							D
C_3							

Gear ratios: R - reverse ($i_G < 0$), U - underdrive ($i_G > 1$), D - direct ($i_G = 1$), O - overdrive ($0 < i_G < 1$), X - locked ($i_G = 0$)

[†] Clutch C_1 connects the links related to the brakes B_1 and B_2 , resulting in the same gear ratio for three modes.

Source: Author.

To numerically validate the kinematic analysis and obtain preliminary transmission ratios, gear teeth numbers assigned to the PGSS are presented in Table 47.

Using the dimensional data in Table 47, lever diagrams were generated for 13 gear modes and are represented in Table 48. The remaining four gear modes are omitted from the table: three are direct drive modes resulting from clutch combinations, and the mode (B_2, B_3) yields the same transmission ratio as the modes (C_1, B_2) and (C_1, B_3) , which are already represented. Due to the two compound links between the

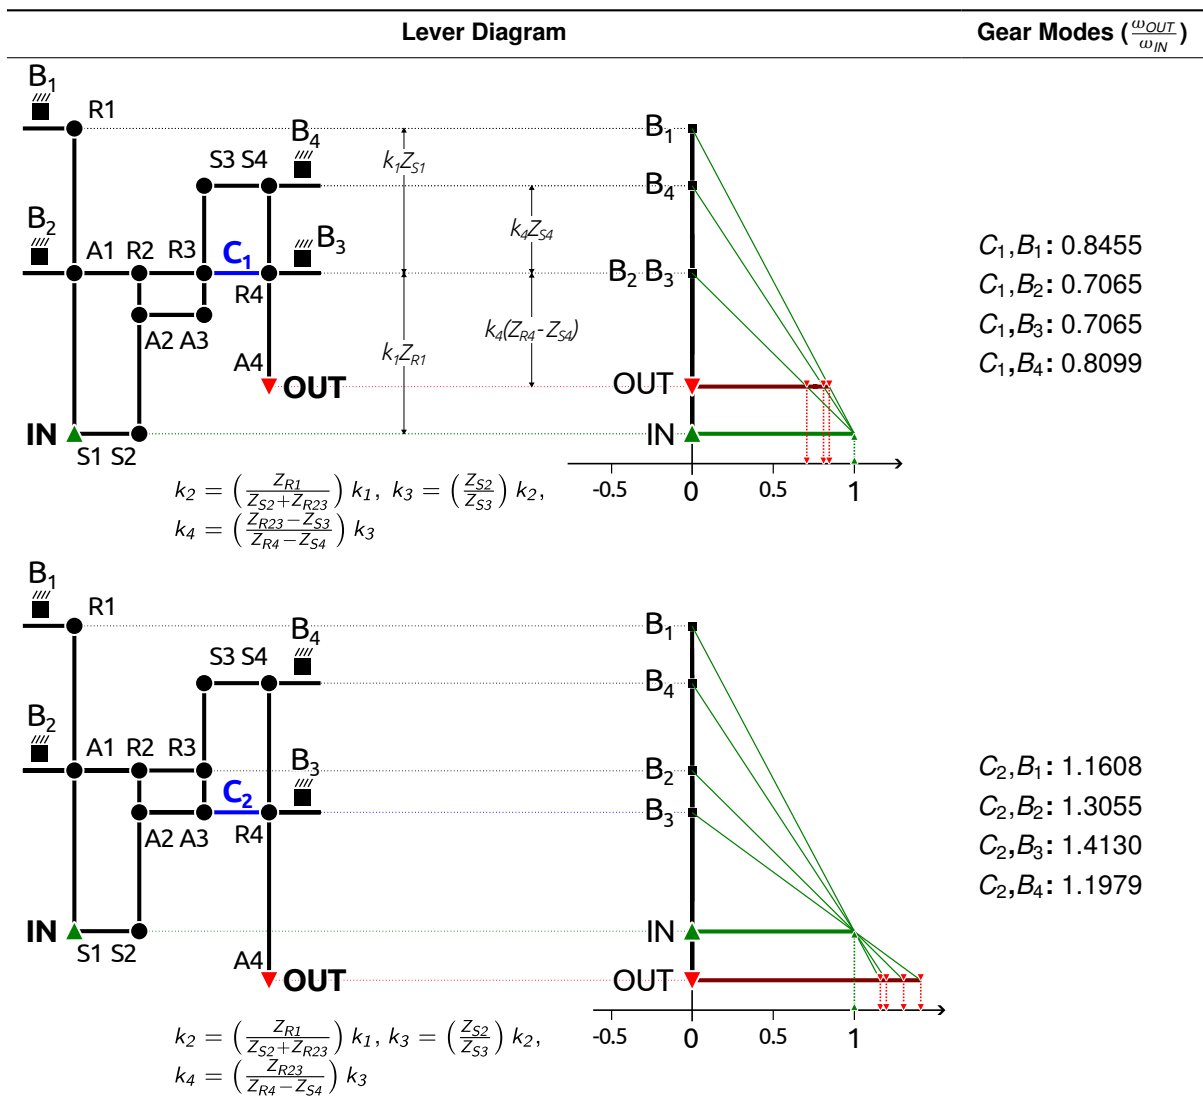

Table 47: Gear teeth suggested for PGM 1S+1D+1R_277.

Simple PGS and the Ravigneaux PGS, scaling constants k_i ($i = 1, 2, 3, 4$) between levers 1, 2, and 3 remain the same for all modes. The scaling constant k_4 for lever 4 (Double PGS) varies depending on the gear mode and is presented in each respective lever diagram.

Table 48: PGM 1S+1D+1R_277 Lever diagrams and gear modes.

Continued on next page

Table 48: PGM 1S+1D+1R__277 Lever diagrams and gear modes. (Continued)

Source: Author.

Lever diagrams are used to illustrate the speed ratios between transmission input and output links. For automotive transmissions, gear ratios are conventionally expressed as the ratio of input shaft speed to output shaft speed (see Section 2.1.1.1). Analysis of individual gear modes within the lever diagrams facilitates identification of shift coupling sequences requiring single transitions and their corresponding gear ratios, as demonstrated in Table 49. The transmission PGM 1S+1D+1R__277 results in one reverse gear and twelve distinct forward gears. An overall gear ratio of $i_{G,tot} = 5.426$ is achieved, and gear steps reasonably adhere to the progressive gear ratio method (Eq. (5)). Among the forward speeds, the first gear provides a suitable reduction with a ratio of $i_1 = 3.840$. Additionally, six progressively reduced gears, three direct drive options, and four overdrive ratios exist. The final overdrive ratio of $i_{12} = 0.708$ falls within the typical range for passenger cars. A drawback of this design involves the transition from fourth to fifth gear (with a ratio of $i_5 = 1.4154$), which requires the simultaneous disengagement and engagement of two shift couplings, disrupting the otherwise simple

transition clutch-to-clutch sequence.

Table 49: Preliminary gear specifications for the PGM 1S+1D+1R__277

Source: Author.

The PGM 1S+1D+1R__277 was generated in two mounting configurations: longitudinal and transverse. The longitudinal version, depicted in Figure 59, features 6 shift couplings (3 brakes and 3 clutches). As the brake B_4 is eliminated in this configuration, it has the potential to produce up to 9 forward speeds - all except gears 3, 6 and 10

of Table 49 - and 1 reverse speed. As a 3-DOF (degrees of freedom) transmission, it requires only 2 active shift couplings for each gear mode.

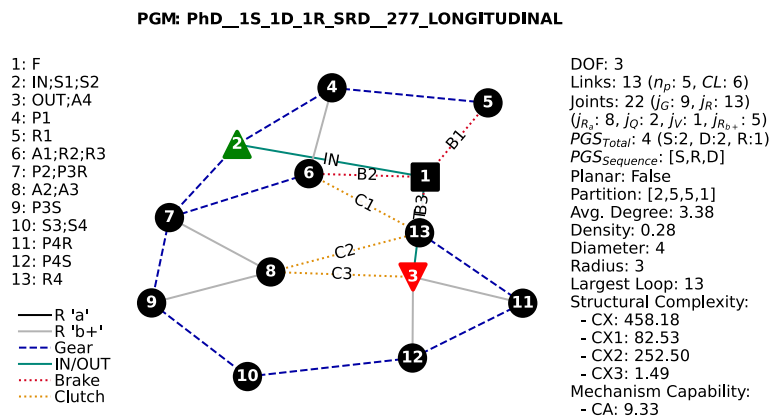

Figure 59 – Diagram of Longitudinal PGM $1S+1D+1R_{277}$.

Source: Author.

The complete graph representation of the PGM $1S+1D+1R_{277}$ longitudinal is illustrated in Figure 60. A detailed evaluation of the mechanism was also introduced, showing it is not planar and have high structural complexity is $PGM_Cx=458.18$, despite its good capability of $PGM_Ca=9.33$.

Figure 60 – Graph of the longitudinal PGM $1S+1D+1R_{277}$.

Source: Author.

The transverse-mount version of the PGM $1S+1D+1R_{277}$, illustrated in Figure 61, differs from the longitudinal version by the addition of brake B_4 within the sun compound link (S3;S4). This modification results in a total of 7 shift couplings (4 brakes and 3 clutches), potentially generating up to 12 forward speeds (7 underdrive, 4 overdrive, and 1 direct) and 1 reverse speeds. Like its counterpart, it is a 3-DOF transmission requiring the engagement of 2 shift couplings per gear mode.

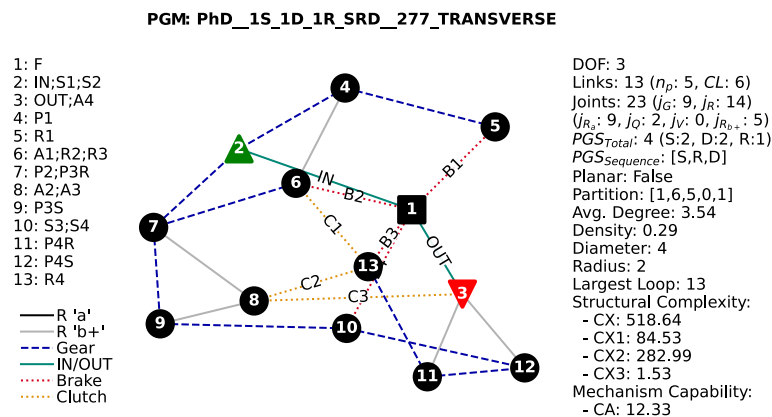

Figure 61 – Diagram of the transverse PGM $1S+1D+1R_277$.

Source: Author.

The complete graph representation of the PGM $1S+1D+1R_277$ transverse is illustrated in Figure 62. A detailed evaluation of the mechanism was also introduced, showing it is not planar and have high structural complexity is $PGM_Cx=518.64$, despite its good capability of $PGM_Ca=12.33$.

Figure 62 – Graph of the transverse PGM $1S+1D+1R_277$.

Source: Author.

Figure 63 displays the possible configurations of the PGM $1S+1D+1R_277$ within the updated technological boundary map. This visualization offers insights into the PGM's potential design space and complexity variations.

Further dimensional synthesis is required to fully evaluate the feasibility of the preliminary gear ratios of Table 49. The absence of these mechanisms in this thesis database suggests potential novelty. To confirm their innovative status and patentability, a comprehensive patent search is necessary.

Figure 63 – PGM 1S+1D+1R_277 in the Technological Boundary Map.

This chapter successfully achieved its objective by demonstrating how the analysis of innovation sets derived from patent database gaps can support the generation of potentially novel planetary gear mechanisms in automotive transmissions. The methodology’s effectiveness was demonstrated by identifying two novel PGMs with promising characteristics for automotive applications.

7 CONCLUSIONS AND FUTURE WORK

This chapter provides a comprehensive summary of the conclusions drawn from the research conducted in this thesis, along with the identification of future research directions. The conclusions address the research questions in relation to the objectives and hypotheses, while also offering recommendations and suggestions for future work. The following sections highlight the objective attainment, acknowledge the scientific contributions made in this thesis, discuss the challenges and limitations encountered, and outline potential topics for future research and development.

7.1 ANALYSIS OF OBJECTIVE ATTAINMENT

This section provides an analysis of the attainment of the specific objectives outlined in the introduction (Section 1.1). A summary of the results is presented in Table 51.

Table 51: Analysis of Objective Attainment

Objective	Attainment	Evidence
1. Investigate analysis and synthesis processes of PGMs	★	Chapters 2 and 3
2. Construct a comprehensive database of PGMs	●	Section 5.3.3
3. Establish a systematic process to identify relevant features	★	Section 4.4
4. Develop an analysis method for identifying innovative gaps	✓	Section 4.5
5. Implement the proposed process in a case study of PGMs	★	Chapters 5 and 6

Legend: ★ exceeded expectations, ✓ complete, ● partial, ✗ not achieved.

Source: Author.

Objective 1, the *investigation of pertinent analysis and synthesis processes* for planetary gear mechanisms, exceeded expectations. This was evidenced by an exhaustive analysis of planetary gear mechanisms, as detailed in Chapters 2 and 3. A comprehensive review of the planetary gear mechanism graph model facilitated the development of a revised mobility equation. This equation, an enhancement of the Grübler-Kutzbach criterion, accurately accounts for redundant and virtual constraints in complex planetary gear mechanisms. Its efficacy was validated through several case studies, significantly enhancing the understanding of kinematics in planetary gear mechanisms. Additionally, new metrics for evaluating mechanism performance, focusing on topological characteristics such as the complexity and capability of PGMs, were introduced, laying a foundation for innovative planetary gear mechanism design.

Objective 2, the *construction of a comprehensive database*, was partially achieved as detailed in Section 5.3.3. The diversity aspect of the database was fulfilled with 186 features, which were later reduced to 143 following data cleansing. However, the extensiveness aspect, essential for fostering innovation, did not fully meet expectations. Out of over 3,500 patents identified as having potential planetary gear mechanisms,

only 160 mechanisms were initially included, and this number was further reduced to 155 due to isomorphism. With this number of instances, although the process is validated, it is not possible to assert that the identified gaps are indeed innovative. Despite falling short of the ideal, the rigorous and time-consuming manual process of dataset generation for each mechanism is noteworthy.

Objective 3, *establishing a systematic approach to identify relevant features*, was exceptionally achieved. In Phase 3 of the process, detailed in [Section 4.4](#), a comprehensive feature analysis was conducted. Through link analysis, complexity metrics, and a technological boundary map, a robust approach for identifying relevant features was established.

Objective 4, *developing an analysis method for innovative gaps*, was successfully achieved on the Phase 4 of the process outlined in [Section 4.5](#). The method identified gaps and provided precise criteria for selecting the most promising innovative sets for design requirements.

Objective 5, *the implementation of the proposed process in a case study*, was successfully achieved as detailed in [Chapters 5](#) and [6](#). Applied to automatic planetary gear mechanisms, the process generated at least thirteen distinct innovation sets with multiple PGSs sequences, providing essential structural requirements for the creation of novel designs. This effort highlighted essential gaps and provided detailed information for guiding design decisions throughout the synthesis process. By focusing on gaps in structural properties on the local context of 10 forward speeds, it was possible to design two potentially new PGMs, emphasizing the value of the comprehensive database and its analyses.

Regarding the overall objective, it can be concluded that it was fully accomplished. This is evident through the identification of innovative requirements that can enable the discovery of potentially new mechanisms not present in the database. The attainment of these innovative requirements demonstrates the successful fulfillment of the general objective.

7.2 SCIENTIFIC CONTRIBUTIONS

The following scientific contributions have been acknowledged in this thesis:

- **Mobility Equation Review:** A comprehensive analysis of the mobility equation, addressing redundant j_Q and virtual j_V constraints, solves the issue of understanding the mobility within planetary gear mechanisms (PGMs) when analyzing the non-actuated mechanisms.
- **Complexity and capability Metrics:** The proposed metrics enable for more accurate comparison between PGMs, providing valuable insights for evaluating technological boundary maps, supporting decision-making during the synthesis process.

- **Process for Identifying Innovation Sets:** A systematic process is devised for identifying innovation sets, integrating the PGM Dataset Template, Attribute Analysis, Gap Analysis, and the application of non-trivial Graph Theory metrics (e.g., Largest Loop, Eccentricity, Centrality). This comprehensive approach enables in-depth analysis of PGMs for determining innovative design requirements.
- **Innovation Sets Concept:** The Introduction of Innovation Sets, aids in identifying and categorizing innovative PGM configurations. This facilitates a structured exploration of potential advancements within the domain of planetary gear mechanisms.
- **Synthesis of New PGMs:** Two potentially novel PGMs were designed in a synthesis process based on innovation sets, demonstrating the effectiveness of the database analysis and discovery process outlined in this thesis.

These scientific contributions enhance the understanding of planetary gear mechanisms and provide valuable insights into their mobility, complexity, and capability. The process developed in this thesis offers a structured approach for identifying and analyzing innovative configurations, contributing to the advancement of planetary gear mechanism research and design.

7.3 CHALLENGES AND LIMITATIONS

This section has highlighted some limitations and challenges encountered during the course of this thesis effort. These limitations include:

- *Limited instances in the database:* The database used in this study contains a relatively small number of instances due to meticulous and time-consuming manual process of converting patents into mechanisms into model datasets. This limitation may impact the generalization of the findings and necessitates caution when interpreting the results.
- *Scope of the solution:* Although the process developed in this thesis is designed to be applicable to various types of mechanisms, the implemented solution presented in this study is specifically limited to Planetary Gear Trains (PGTs). Further adaptations and modifications would be required to tailor the process to other types of mechanisms under investigation.
- *Technical expertise required:* The analysis and characterization of PGMs demand a high level of technical knowledge, which may limit the widespread adoption and use of the process. The successful application of the process relies on individuals with a deep understanding of the technical aspects of gear trains.

These limitations and challenges provide valuable insights into the boundaries and potential areas for improvement in this research. Addressing these limitations will contribute to the refinement and further development of the process, enhancing its

applicability and expanding its utility to a broader range of mechanisms.

7.4 FUTURE WORK

The following list outlines potential avenues for future research and development:

1. **Automate Data Collection:** To enhance the comprehensiveness and representativeness of the database, future work should focus on automating data collection processes. Specifically, improvements can be made in patent search accuracy and the conversion of patent designs into model datasets. Patent search is a labor-intensive task that requires significant manual effort and time for researchers to filter relevant results and convert images and claims into mechanism representations. The use of techniques such as classification models using KDD (WOLSKI et al., 2023) and image and claim conversion automation can help expedite this process with accuracy. By automating these tasks, a larger number of instances can be included in the database, facilitating more robust analyses and improving the scalability of the mechanism survey.
2. **Expand the characterization of PGMs:** In addition to the existing features considered for PGM characterization, future studies could include additional metrics such as efficiency analysis (LAUS et al., 2012). Incorporating efficiency measurements would provide a more comprehensive understanding of the performance characteristics of PGMs and enable more precise comparisons and evaluations.
3. **Designing new PGMs:** Expanding the PGM database to identify innovation sets with greater innovation potential and synthesizing new automatic transmissions.
4. **Enhance complexity metrics:** To further refine the complexity assessment of PGMs, future work should consider including detailed project information such as dimensions, manufacturing processes, costs, and other relevant factors. This additional information would provide a more nuanced evaluation of the complexity of PGMs and aid in decision-making processes related to design and optimization.
5. **Improve capability metrics:** The capability analysis of PGMs can be enhanced by incorporating efficiency as a metric. Efficiency measurements would capture the energy losses and power transmission capabilities of PGMs, enabling a more comprehensive assessment of their overall performance.
6. **Automation of innovation set analysis using matroids:** Future research could explore the use of matroids, a mathematical framework, to automate the analysis of innovation sets. Matroids can provide a systematic and efficient approach to identify innovative configurations within the design space, streamlining the innovation discovery process.
7. **Generalize the process to other complex mechanisms:** The developed pro-

cess has the potential to be extended to the synthesis and analysis of other complex mechanisms beyond PGMs. Future studies could explore its application to diverse systems such as hybrid gearboxes, robot parallel manipulators, or any other mechanical devices. This expansion would further validate the process's effectiveness and broaden its practical utility.

8. **Utilize graph representation learning (GRL):** Instead of converting the graph representation of mechanisms into conventional data structures, employ specific methods designed for graph data structures in knowledge discovery and data mining (KDD). GRL models ([HAMILTON, 2020](#)) facilitate the computation of graph embeddings that capture the topological, structural, and semantic relationships of the graph. This enables various tasks, including visualization, clustering, and prediction of node and edge labels. State-of-the-art algorithms in GRL, such as GRAPE ([CAPPELLETTI et al., 2023](#)), have demonstrated their effectiveness in diverse domains such as sociology, biology, medicine, and others.

These future research directions aim to enhance the process, broaden its scope, and enable its application to a wider range of complex mechanisms. By addressing these areas, researchers can further advance the field and uncover new insights and innovations in mechanism design and analysis.

Appendix

APPENDIX A – PLANETARY GEAR MECHANISMS DATABASE

This appendix is dedicated to presenting the construction of the database using the PGM dataset template and details each of the 159 PGM datasets used throughout the thesis to demonstrate the application of the process proposed in the Chapter 4.

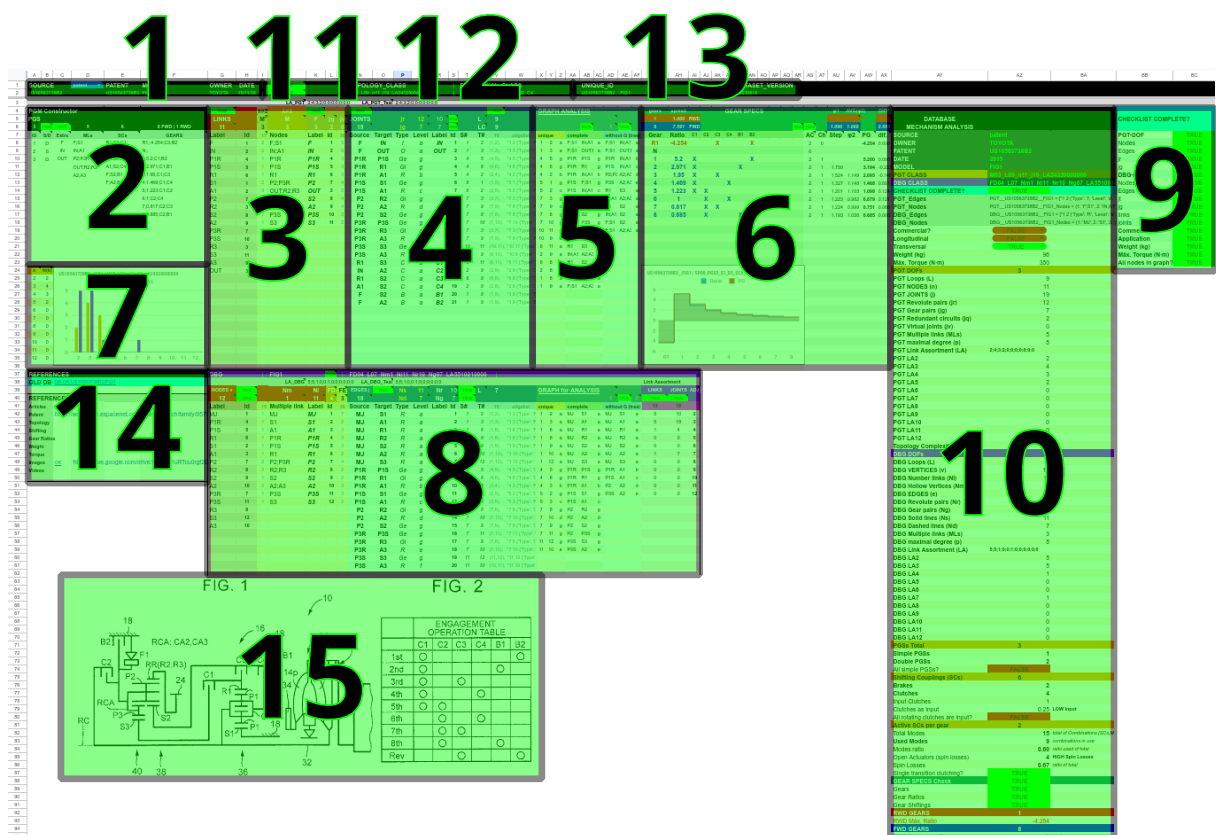

A link to the Google Drive folder containing all datasets is available at [PGM Datasets folder](#).

The complete database can be found in the [PGM Complete Database Spreadsheet](#).

A.1 PGM DATASET TEMPLATE

As described in the Section 4.2.3 section, each PGM collected data was input into a worksheet template that automatically generated its corresponding dataset information. For reasons of space, the dataset template for the sample of Figure 45 is detailed in 15 sectors, arranged in a Google Sheets spreadsheet according to the map shown in Figure 64. This dataset is available at [US10563738B2__20230618](#).

A.2 PGM COMPLETE DATABASE

The complete database employed for this thesis is comprised of 159 PGMs of automatic transmission. For each model is presented the identification, topological, and functional data, besides the mechanism functional diagram, the PGM graph, and the DBG graph. Following, the instances are presented and identified by their respective *UNIQUE_ID*.

APPENDIX B – VISUAL RESULTS FROM THE PROCESS APPLICATION

In the journey of scientific exploration, visual representations often bridge the gap between complex data interpretations and a clear understanding of the underlying phenomena. This appendix is dedicated to presenting a comprehensive collection of charts resulting from the application of the process in [Chapter 5](#). Each chart serves as a visual testament to the intricate processes, analyses, and findings detailed in the preceding sections. Readers are encouraged to refer to these visual aids to enhance their comprehension and appreciation of the data science techniques employed and the insights gathered from them.

The database containing all [PGM](#) data after cleansing ([Section 5.4.1](#)) is available in [PGM Prepared Database Spreadsheet](#).

The [PGM](#) correlation matrix of the database, containing all correlations ([Section 5.4.2](#)), is available in [PGM Database Correlation Matrix Spreadsheet](#).

In the following pages, the results of the univariate, bivariate and multivariate data analysis of [PGMs](#) ([Section 5.4.2](#)) are presented in corresponding sections.

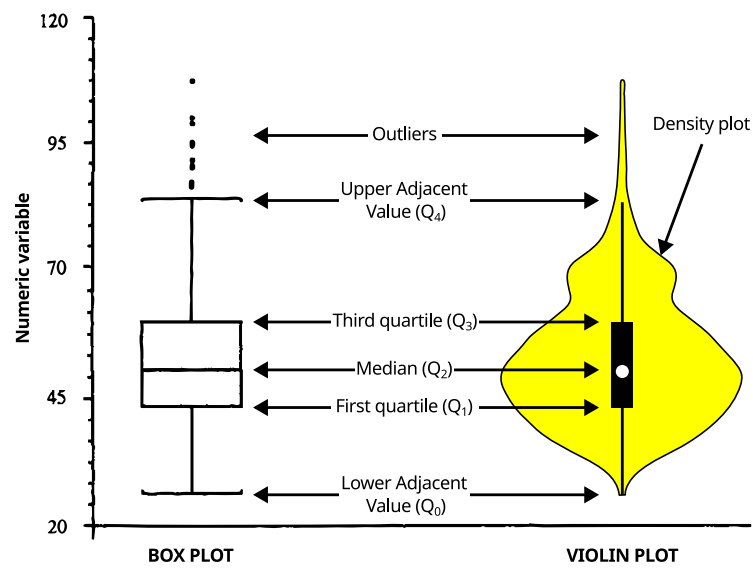

B.1 RESULTS OF UNIVARIATE DATA ANALYSIS

The results of the univariate data analysis discussed in [Section 5.4.2](#) are presented in representative graphs according to each feature data type.

For numerical values, it was utilized the violin plots that merges the characteristics of a boxplot with a smoothed probability density function, offering an unbiased visualization of data distributions ([HINTZE; NELSON, 1998](#)). It highlights key statistical markers like the median, quartiles, and extremes, making it ideal for graphically examining and comparing multiple data sets as shown in [Figure 241](#).

The features analyzed were segmented by three main characteristics: number of forward gears, number of total [PGSs](#), and the commercial status.

B.3 RESULTS OF LINK ANALYSIS

The Frame (F), Input (IN), and Output (OUT) links were analyzed to determine their compound compositions, adjacency connections, and centrality measures. The results were segmented by three primary characteristics: the number of forward gears, the total count of [PGSs](#), and the commercial status. Graphical representations of these results for each link are provided in the following sections.

B.3.1 Frame (F) Link Results

B.4 RESULTS OF FEATURE SELECTION

The 15 most relevant features selected through four methods and two aggregators for each target feature discussed in [Section 5.4.4](#) are detailed in this section.

Function Overview

It was developed a Python function to execute a series of steps, each contributing to the overall objective of identifying and ranking the most significant features for a given target feature in the [PGM](#) database. Four methods are employed to assess feature importance:

- *Random Forest Classifier*: Utilized for its inherent ability to provide feature importance, this method offers a view based on ensemble learning.
- *Recursive Feature Elimination (RFE)*: This technique uses Logistic Regression to iteratively remove features, focusing on those that contribute most to the prediction accuracy. As RFE importance results in a ranking, features with lower ranking implies greater importance.
- *Univariate Statistics*: F-scores for numerical features and Chi-squared scores for categorical features provide a statistical basis for feature selection.
- *L1 Regularization (Lasso Regression)*: This approach highlights features that remain significant even after applying regularization, which helps in reducing overfitting.

The function synthesizes information from the various methods into two aggregated rankings:

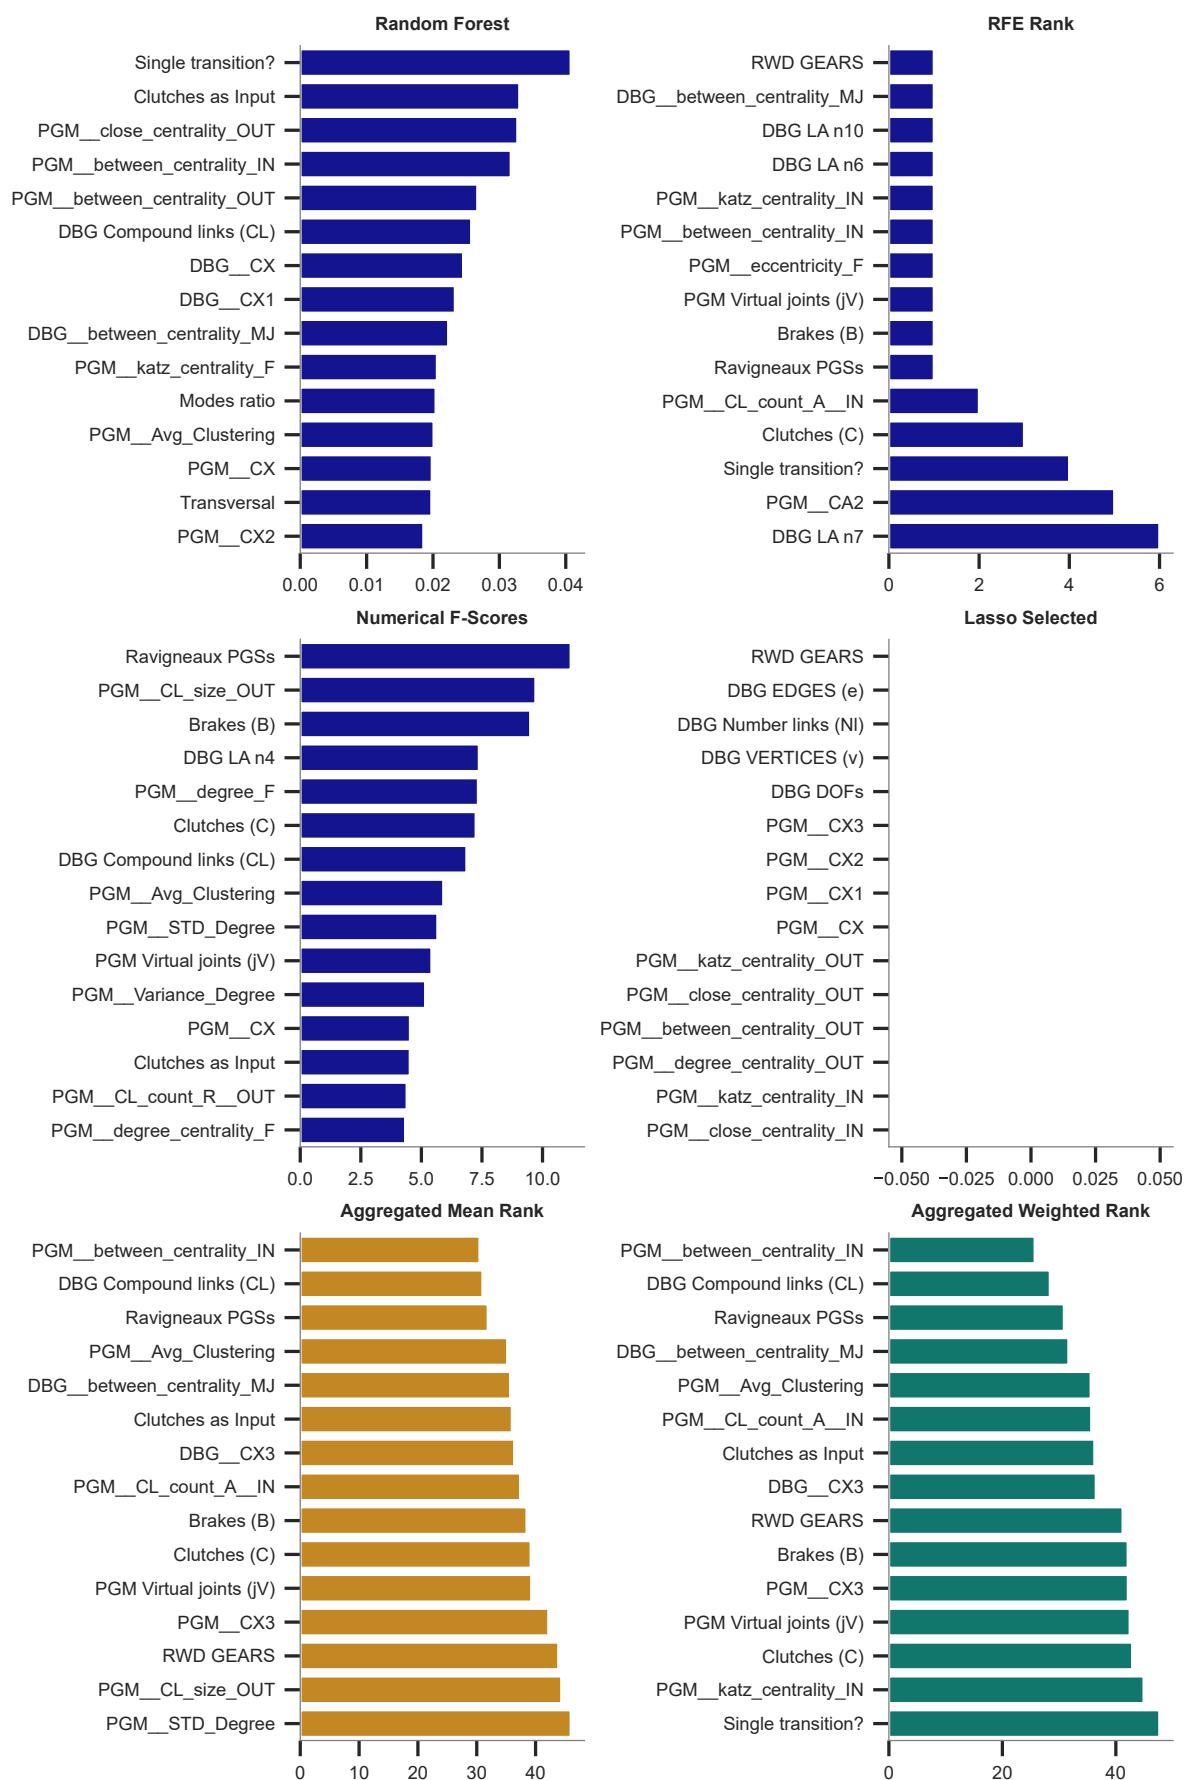

- *Weighted Ranking*: This combines the different rankings, emphasizing the methods considered more reliable, with predefined weights: $\text{Weighted Rank} = 0.35 \times \text{RF} + 0.35 \times \text{RFE} + 0.1 \times \text{Lasso} + 0.2 \times \text{F-Scores} + 0.2 \times \text{Chi-Squared}$
- *Mean Ranking*: Averages the rankings from each method, providing a balanced view across all techniques.

Visual representation provides clear, comparative bar charts for each method's feature importance and the aggregated rankings.

Results by target feature

The outcome of this function is a comprehensive ranking of the 15 most relevant features based on multi-faceted approach to reduce the risk of bias inherent in any single method and to provide a robust basis for selecting features for further [PGM](#) design requirements. The visualization of the results for each target feature is presented below.
